At once let me say I have some sympathy with Sir Arthur Hurst, and I have no hesitation in observing that in this country there is probably more inferior work turned out in examinations by the opaque enema than in any other branch of radiology. We do not require to search far for the reasons, and two prominent causes for this failure to my mind are outstanding. These are lack of thorough preparation of the patient and incomplete thoroughness of the radiological technique. Mild aperients should be employed for premedication and on no account strong irritant drugs such as castor oil. The latter when used perhaps cause more cases of gas collection and spasm than is generally appreciated. The preliminary "wash-out" of the bowel should be done with plain warm water and preferably by the Studa chair method. On no account should irritant substances such as soap be included in the "wash-out." Since the soap-and-water enema was discontinued at St. Mark's Hospital some years ago cases of spasm of the bowel are rare. As to technique, space does not permit detailing some of the important features, but I would stress the importance of the oblique views and particularly the left oblique. Time and time again when nothing is found in the straight postero-anterior views an early carcinoma is demonstrated in one of the oblique views. Inflation of the bowel with gas after the enema in the majority of cases is of limited value. In early carcinoma it is, in fact, misleading, but in cases of multiple diverticulosis it does further balloon out the sacs of the diverticula and help to clinch the diagnosis.

During the past fourteen years, while in charge of the x-ray department at St. Mark's Hospital, operative findings on all cases that have been examined by an opaque enema are returned to the department. The records show that out of 2,200 opaque enema examinations only four cases of missed x-ray diagnosis are recorded. Of the four two were suspected and the enema repeated but the growth not demonstrated. The growth in the third was obscured by a greatly distended bowel; and in the case of the fourth, a double carcinoma on the posterior wall of the sigmoid flexure, the bowel assumed that elastic expansile feature, and kept the growths hidden behind the redundant loops of the pelvic colon even after the administration of the third opaque enema. All these cases were operated upon and the growths removed.

On the other side of the balance-sheet could be enumerated various cases of how an opaque enema established a diagnosis quite unsuspected clinically; confirmed a clinical suspicion, or corrected a clinical diagnosis from one of carcinoma to one of diverticulosis, or vice versa. In one case a slowly growing carcinoma was watched from its very earliest stages over a period of three years by a series of opaque enemata at a few monthly intervals. The growth was eventually removed, and seven years later the patient, a doctor running a large practice, is in perfect health. Apart from saving the patient's life the series of examinations was most instructive as to the radiological changes of a very early growth.

It might therefore be correct to say that the opaque enema is of the greatest value as a diagnostic agent if a positive finding is recorded. On the other hand, if the result is negative, on no account should it be accepted that early pathology has been finally disposed of, but the physician or surgeon must make his final decision as to diagnosis on his other clinical findings.

This subject is too vast to cover in the space at my disposal, but I have in the process of writing a book on this work in which I hope to introduce some new appliances and modern points in technique, which may help to reassure the few who may have become depressed about the shortcomings of the older technique.—I am, etc.,

London, W.1.

NORMAN P. HENDERSON.

Resuscitation by Rocking

SIR.—The method of attaching the stretcher to the trestle or whatnot is the crux of the business from the practical point of view. (It is, e.g., easy enough to see what the Kilmarnock gadget looks like when finished, but how it is made I cannot make out at all! Another stretcher was illustrated a few weeks ago, and all but the attachment was plainly shown!)

A standard A.R.P. stretcher hung in a hook at the end of a rope, which in turn hangs from a hook in the ceiling, slides backwards and forwards in the hook, to the damage of the wire, etc. Also the whole affair tends to swing about. We have therefore hung a festoon of rope from the ceiling, from two hooks, which stops the swinging, and have got our blacksmith to form the hooks as shown in the accompanying sketch. I don't think anything could be simpler or more quickly brought

into action. Each limb of the hook comes against one of the clips which attach the meshwork to the side member of the stretcher. This stops the sliding. (Iron or mild steel 3/16 x 1 in.)

We have tried the "swing-boat" suspension also, and can confirm that it is absolutely useless if merely rocked to and fro. There is neither impulse to viscera nor effect of gravity.

Its efficiency may, however, be very great, but this can only be achieved by the forcefulness of the push-off from the middle position and the forcible arrest in its return transit; and the effect of gravity can only be obtained by holding the whole affair up for an appreciable time at the ends. Obviously, for a full-grown patient this means really hard work. The effects will be in proportion to the force used, and no more.

Now as to the attachment of the patient to the stretcher—Siebe-Gorman, in a catalogue I have, picture him on their rocking-stretcher held by a sort of yoke over the shoulders and two bands through between the legs high up. I do not know whether they have an alternative, but this must surely tend to crush the body together, whereas fastening by feet at one end and hands extended to the full beyond the head at the other (as recommended by Dr. Eve) will tend to open out the trunk. An ordinary A.R.P. stretcher is much too short to secure a full-sized person in this way, so here is a sketch of our expedient. The timbers are fitted with pegs, which project down through the meshwork, and so long as they are kept down they remain perfectly firm. If neither patient nor his wrappings suffice for this, a turn of twine tied through will suffice.—I am, etc.,

Doncaster.

W. REGINALD WILSON.

Medical Boarding for the Merchant Navy

SIR,—On taking up duty recently as ship surgeon in a large liner engaged in carrying troops I was greatly puzzled and surprised at the number of men wanting to "sign off" the ship's articles immediately before we were due to sail. Most trivial ailments were professed as the urgent necessity for being put ashore.

All seamen to be "signed on" as a ship's crew are passed through the Merchant Navy Reserve Pool. On being "signed off" on completion of the voyage they are again received into the pool and draw, I believe, a reasonably generous rate of pay until re-employed. Many men appear to remain in the pool drawing regular pay for long periods without work. Certain members of my crew attempted to get ashore with some trivial excuse after having signed the ship's articles, being conveyed some hundreds of miles by train, and being fed and accommodated and paid for a fortnight or so in harbour. On being "signed off" they again report to the pool, and then, I suppose, say they have recovered from their temporary disability for which they were "put ashore by the doctor," and again become eligible for the benefit of pool pay. Another ship may be available in the near future or there may be a long waiting period—on pay. The same scheme of "paying off" may work again.

These men may or may not be examined by the "Federation" doctor before being granted pool pay. I do not know. I believe only a very small percentage of the men are actually examined before being sent to join a ship, and those who are examined appear to undergo a most cursory examination by a single doctor. In order to put an end to this racket it is surely essential to have a proper and thorough standard examination of all seamen such as we have under the National Service scheme for all Service personnel and the Home Guard. Is not the Merchant Navy an integral part of the fighting Forces? Grade cards should be issued. Certain men should be definitely debarred from going to sea in justice to themselves, and others, because of some such infection as tuberculosis or certain skin diseases, on account of the risk and unpleasantness for their shipmates. Some men physically unfit for strenuous work as A.B.s might well be suitable for employment as stewards or in some other capacity. To expect efficiency from the "scratch" crews of physically miserable specimens such as are being recruited to the Merchant Service to-day is absurd.

I believe that the standard of Merchant Navy crews to-day, physically and otherwise, is very much below that of peacetime. Many of the best men are serving with the Royal Navy, but the fact of a magistrate recently remitting sentence on a convicted man on condition that he joined the Merchant Navy does not reflect very handsomely on the Service. This caused considerable resentment. I suggest that it is a most urgent matter to have all men who are in the reserve pool awaiting employment at sea properly examined by a medical board and not merely "passed," as may be occasionally required by a single "Federation" doctor. Medical boards are in being

all over the country, and it would be a very simple business to arrange for the examination of these seamen—and it should be a Government responsibility.

On my recent voyage one most impertinent youth produced a letter from a doctor recommending x-ray examination of chest every 3 months. Six months had elapsed and this produced on the day of sailing with a demand to be "signed off." He made other excuses and was a very definite malingering or "wangler." Another man with chronic bronchitis and emphysema spent part of the voyage in the ship's hospital. Such a man would never be passed by a National Service Board. Many men with disgracefully carious teeth wished to go ashore to have their teeth attended to. This treatment is very necessary, but there is no means of seeing that the treatment is carried out. There should be some regulation enforcing necessary treatment before a man is accepted into the pool. Some men complained of abdominal pain and demanded to be put ashore for x-ray examination. Most of these, I am convinced, were malingerers. A number suddenly requested "sign off" on account of deformities and disabilities, such as varicocele, varicose veins, and congenital deformities of feet, which had not really troubled them for years. A proper system of medical examination and a properly kept medical record card would control the endeavours of these men to shirk their duties.

Briefly, all men in the Merchant Navy Reserve Pool should be passed by a properly constituted medical board and compulsorily a medical record card, which should be kept to date by the ship surgeon or by the Federation doctor at the time the man passes through the pool. Any necessary treatment—such as dental extractions, fillings, or other operations—should be undertaken before a man is entitled to benefit from pool pay, or be instituted without delay on leaving a ship. Special arrangements might be made with certain hospitals, new treatment centres opened to avoid a seaman having to loaf about awaiting treatment at an overcrowded hospital with a long waiting list. With more physical fitness and discipline the status and morale of "His Majesty's Merchant Navy" would be more worthy of the name.—I am, etc.,

Huddersfield.

S. H. WADDY.

Nurses' Pay and Hours

SIR,—Two recent committees have managed to raise the economic status of the nurse from that of a lavatory attendant to nearly that of an L.P.T.B. railway porter. It would be an exaggeration to say that the labours of these committees have resulted in a "nurses' charter"; but they have at least proved one thing. This is, that nurses have little to hope from the seniors, their "employers," or the medical profession, who are much too worried about the future of their own sixpences and guineas to devote much time to the rights of their sister profession.

The truth is that nursing is the only indispensable profession in the modern world. The medical profession, in its present state, takes a far lower rank. It is undergoing its "twilight of the gods." In any case the nurse goes through a more exacting training than the medical students, and survives much more troublesome tests before she is qualified. She earns 90% of all medical knighthoods, baronetcies, and even peerages. She cannot reach a competence of £300 a year without displaying qualities of mind and soul that would disqualify Winston Churchill or Franklin Roosevelt. Yet she is treated at the best like an irresponsible schoolgirl and at the worst like a Czech in a German labour camp. She is not considered fit by the "bumbles" who control her destinies, to take any part in the social life of her time, and, God knows, she could tell us a thing or two. One consequence of this is that by the time she reaches the upper ranks of her profession she has the social outlook of a tame elephant.

Her time to act is in the early thirties, or even earlier than that. And she must act for herself. Dr. McKean and I at sincere well-wishers, but all we can supply is a little invective. A dozen young women of the nursing profession must get together and tell the whole body politic of these islands that they have had enough nonsense. They know how to deal with stupid, conceited, and refractory patients, and that is what we all are.—I am, etc.,

Bearsden, Dunbartonshire.

O. H. MAVOR.

The Spackman Case

SIR.—With reference to the recent case in the House of Lords of the G.M.C. v. Spackman, we would like to bring forward the following points for consideration.

1. As the rules of conduct of the G.M.C. appear, from the defence in the above case, to be most arbitrary and despotic—trial of the admission of fresh evidence, denial of the right of appeal—it is surely time for a reconstruction of these rules. Can machinery be evolved whereby evidence before the G.M.C. must given on oath?

2. From what source does the G.M.C. derive any income? What do or bodies have control of such moneys? In the above case: decision of the G.M.C. to take the inquiry to the House of Lords after receiving an adverse decision in a lower court savours almost inquisitorial ferocity, in addition to the fact that such assures must dig deeper into the financial resources of the Council the final decision be unfavourable.

The fact that the *Times* of Aug. 6 sacrificed a whole column its drastically reduced publication to the reporting of the decision of the House of Lords shows that public interest is aroused, and the reaction of the public to the conclusions, naturally arrived at by them, of the case must be that the Council have conducted themselves in an unfair and prejudiced manner. It is surely such behaviour in the international sphere at we are fighting to suppress, and it behoves us to press different methods in our own domestic back-garden before stand out for justice in the wider fields.—We are, etc.,

R. A. P. CORKERY. P. BOBBETT.
DOROTHY G. HERVEY. J. F. LINEEN.

Doctors for China

SIR.—In the spring of last year you inserted in the *Journal* letter from me asking for offers from doctors and nurses for service in a Red Cross hospital unit in China. Twenty-one were selected and sent out under Dr. W. S. Flowers and have established a base hospital at Changsha, Hunan. Sick and wounded, both civilian and military, are being treated and excellent work is being done.

An appeal has now been received by the War Organization of the British Red Cross and St. John for reinforcements. It is especially desirable that applicants should have a knowledge of the Chinese language or a background of Chinese experience. Further particulars may be obtained from Dr. H. Gordon Thompson at the headquarters of the War Organization of the British Red Cross and St. John, 14, Grosvenor Crescent, London, S.W.1.—I am, etc.,

London, S.W.1.

HORDER.

Advice on how local authorities can make fuller use of their powers under the Prevention and Treatment of Blindness (Scotland) Act is contained in a recent circular of the Department of Health. Local authorities should make wider use of special schools and classes for children whose eyesight is defective—arrangements being made with neighbouring authorities where necessary—and of residence in country homes for those whose eye troubles are the result of general debility. There should be closer contact with industrial medical services so that children leaving school are not given jobs that impose heavy demands on defective sight, and more facilities for expert consultation and for treatment of infections responsible for blindness. The circular is the outcome of analyses of the experience of the regional clinics for certification of the blind in Scotland, and particularly of a statistical analysis by Marshall and Seiler, based on the results of examining 3,219 certified blind persons in Glasgow and South-West Scotland. Cataract, myopia, optic nerve atrophy, ulcer of the cornea, glaucoma, and iridocyclitis were found to be responsible for about three-quarters of the cases of blindness. The circular points out that several of these conditions are amenable to treatment, while existing services of local authorities can play a part in preventing others. Early energetic treatment by modern methods, it continues, can prevent the onset of blindness in practically all cases. Even in degenerative diseases leading to blindness in later life many of the conditions can be alleviated by expert care; Drs. Marshall and Seiler concluded that there was still the possibility of restoring vision by operation in more than half of their cases of blindness due to senile cataract. They found, too, that patients with conditions associated with pain or sudden onset were more likely to seek advice than those with insidious onset arising later in life, and that the proximity of hospital facilities affected the numbers seeking treatment.

Obituary

Dr. LOUIS INGRAM DUNCAN, who died at Higher Brixham, South Devon, on July 12, was born in Aberdeen on August 24, 1898, son of the late George Duncan, and was educated at Inverurie Academy and Aberdeen University, where he graduated M.B., Ch.B. in 1921. Dr. Duncan formerly practised in partnership at Port Talbot, Glamorgan, and was teacher of ambulance and hygiene under the Glamorgan County Education Authority. After moving to South Devon he became one of the medical officers to the Brixham Hospital.

We regret to announce the death on July 17 after a long illness of Dr. CECIL WESTLAND PILCHER, consulting surgeon to the Boston Hospital and one of the oldest and most respected members of the local Division of the B.M.A. His father was a well-known general practitioner and surgeon at Boston. From Bath College he went to Keble College, Oxford, with a classical scholarship; he took his B.A. in 1893 and came to London to study medicine at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1899. Dr. Pilcher was an honorary captain in the old Lincolnshire R.A.M.C.V., and during the last war served as civil medical officer in charge of troops, being awarded the M.B.E. for his services in 1914-19. For over 30 years he was divisional surgeon for the local Branch of the St. John Ambulance Brigade. He was an accomplished amateur artist, and several of his works were accepted by the Royal Academy and the Royal Society of Painters in Water-colours. He joined the B.M.A. in 1903, and in 1926-7 held office as chairman of the Holland Division, which he had represented at the Annual Meeting at Oxford in 1904. He was a faithful attendee at medical meetings, which he used to enliven by good-humoured caricature sketches of his neighbours. His son, Mr. R. E. M. Pilcher, F.R.C.S.D., is honorary surgeon to the Boston Hospital and Spalding Hospital.

Dr. JAMES M. FERGUSON, one of the staunchest supporters of the B.M.A., died on July 24 in the Victoria Hospital, Burnley, at the age of 86. Born in Bolton of Scottish parents, he began life in a humble job in the printing office of the *Warrington Guardian*. After three years as a compositor and occasional reporter he entered as a medical student at Owens College, Manchester, and qualified L.R.C.P.Ed. in 1882, afterwards taking the L.R.C.S.Ed. and the D.P.H. of Durham. As was possible in those days, he gained experience of practice in Burnley and elsewhere as an unqualified assistant. In 1885 he set up on his own account in Burnley, where he became medical inspector under the Factories and Workshops Act, and later medical officer for the local joint hospital board, and medical superintendent both of the district sanatorium and of the small-pox hospital. Dr. Ferguson served the borough as councillor and alderman and was appointed to the magistrate's bench in 1903, so that at the time of his death he was the senior J.P. for the borough. He was highly respected in the town and his kindly and jovial disposition made him popular everywhere. He joined the B.M.A. in 1886, represented the Burnley Division at four Annual Representative Meetings, and held office as its honorary secretary and later its chairman. He was president of the Lancashire and Cheshire Branch in 1911. Though it is some years since Dr. Ferguson took a very active part in the meetings of the Burnley Division, he yet kept in touch with local medical matters, and particularly with B.M.A. doings. Throughout his life he was a keen sportsman, and in the 'nineties played cricket regularly; in later years he devoted much of his leisure time to fishing.

Dr. W. WILTON JOHNS, who died in a nursing home in Edinburgh on July 26, had practised in the Morningside district for the last eighteen years. After qualifying L.R.C.P., L.R.C.S. from Edinburgh University in 1906 and taking the M.B., Ch.B. of that university the following year, he held a house appointment at the Dumfries and Galloway Royal Infirmary. He took his M.D. in 1910. For some years he was in practice at Nairn, where he was also honorary medical officer to the Nairn Town and County Hospital. In 1925 he went to Edinburgh to assist the late Dr. James Graham, and was practising in the Morningside district at the time of his death. Wilton Johns made friends easily, and his sympathetic manner with children accounted for much of his success as a surgeon for 10 years to Donaldson's Hospital. He served as captain, R.A.M.C., in the last war; and was also civil surgeon to the Edinburgh and Border Hospital, Dunkirk, from 1914-15. He is survived by an only son, who is in his fourth year of medicine at Edinburgh University.

Dr. JOHN GILMOUR, who died at Glasgow on July 27, joined his father in practice at Duntocher in 1893, having graduated M.B., C.M. with high commendation at Glasgow University in 1891. He moved to Dalmaur in 1901, and established a large practice in the Duntocher, Clydebank, and Dalmaur areas. In 1908 he took the F.R.C.S.Ed., and in 1911 the D.P.H. of Cambridge with distinction. He was elected a Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow, in 1930. After many years of successful general practice he was appointed in 1921 to the staff of the then Scottish Board of Health when the Regional Medical Service was started. He was posted to the South-Western Area, with headquarters at Glasgow, and his good work and the high esteem in which he was held did much to establish the new service in the good graces of the profession. He retired from the service in 1936, but on the outbreak of war offered to forgo his leisure in order to enable younger colleagues to take up work directly concerned with the war. He superintended the Clyde Basin experiment designed to provide a consultant service for war workers, and was largely responsible for its success. He was without enemies, and his friendship was highly valued, as was his clinical acumen. Dr. Gilmour, who was awarded the O.B.E. in the New Year Honours List this year, served as a member of the Home Office Commission on the Workmen's Compensation Act and Miners' Nystagmus. He is survived by two daughters and a son, Dr. Alan Gilmour.

One of the longest-lived dispensary doctors in Ireland passed away recently in the person of Dr. JOHN POYNTZ RICE. Educated at Clongowes and Queen's College, Cork, he qualified in Edinburgh in 1883. He was appointed dispensary medical officer for Castleisland in 1889, and this position he held for 50 years, retiring in 1939 to a well-earned rest at his favourite hobbies, gardening and farming. He was an ardent supporter of the Royal Medical Benevolent Fund and had been a member of the B.M.A. for many years.

Dr. D. L. T. MACSHERRY, the only surviving son of Dr. and Mrs. Maurice Macsherry of Edgbaston, Birmingham, was killed by enemy action at sea in April, 1943, aged 26 years. He became a surgeon in the Merchant Navy after qualifying M.R.C.S., L.R.C.P.Lond. in 1942.

The following well-known medical men have died abroad: Dr. LESLIE LAWSON BIGELOW, clinical professor of surgery at the Ohio State University College of Medicine and president of the Ohio Medical Association, aged 62; Dr. ELMER BURKITT FREEMAN, clinical professor of gastro-enterology at the University of Maryland School of Medicine, aged 67; Dr. FRÉDÉRIC GUYOT, one of the founders of the Geneva Society of Oto-rhino-laryngology; Dr. NATHAN LÖWENTHEL, honorary professor of medicine at Lausanne University, aged 87; Prof. HEINRICH ZÖRNIG, formerly professor of pharmacology at the University of Basle and founder of the Basle Pharmaceutical Institute, aged 76; Dr. ANDRÉ TOURNADE, professor of physiology at the University of Algiers from 1920 to 1942, aged 62, whose chief work was connected with the physiology of the suprarenals.

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

M.D.—Branch I (Medicine): A. J. W. Beard, J. V. Davies, P. Fränkel, Frances V. Gardner, Joyce A. Keeping, Frances J. Pounds, Branch II (Pathology): V. H. Bowers, S. D. Eick, J. L. Peniston, R. E. Rewell, Branch IV (Midwifery and Diseases of Women): J. C. Adams, Branch V (Hygiene): C. E. E. Harrington, D. P. Holmes, B. A. Thomas, Branch VI (Tropical Medicine): W. J. S. Wilson, ACADEMIC POSTGRADUATE DIPLOMA IN MEDICAL RADIOLOGY.—H. H. Hermann, D. D. A. Jayamanne, B. Sandler, L. M. Shorvon, Part I: M. Sheehan.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

The following scholarships, exhibitions, and prizes have been awarded:

Goldsmith Entrance Scholarships: (1) D. R. Smith, Caius College, Cambridge. (2) Miss P. A. Howard, Newnham College, Cambridge. Goldsmith Entrance Exhibition: Miss M. B. Robinson, Lady Margaret Hall, Oxford. Atchison Scholarship: Miss Geraldine M. Howard, Magrath Scholarships: Medicine: A. N. Smith, Midwifery: Miss Geraldine M. Howard, Erichsen Prize: K. Chitty, Liston Gold Medal: P. H. Jones, Fellowes Gold Medal: J. S. Crowther, Fellowes Silver Medal: H. Kaufman, T. H. Powell, Wilfred Trotter Medal: T. H. Richards, G. R. Parry, Suckling Prize in Obstetrics and Gynaecology: L. M. Gerlis, F. T. Roberts Prize in Obstetrics and Gynaecology: H. E. Thomas.

Medical Notes in Parliament

House of Lords on Government's Milk Policy

In the House of Lords on July 27 Lord ADDISON called attention to certain aspects of food policy, with special reference to milk and milk products, and their cleanliness and safety. He welcomed the White Paper, and said it represented a great step forward. It meant that the State was going to see that this vital food not only became more popular but was also wholesome. Speaking as a member of the medical profession, he said that a great deal of nonsense had been talked about damaging milk by pasteurizing it. He was glad that arrangements were foreshadowed for sterilization by pasteurization as and when it was practicable to do so, could not be done all over the country at once, and he gathered that the Minister would begin with the larger centres of population. It would need courage and persistence, but he knew nothing so far as the improvement of diet and nutrition was concerned which had given him more encouragement for many years than this enterprise.

Lord HORDER said that many who had, on medical grounds, urged for some time that steps should be taken along the lines felt on the whole satisfied with the policy outlined in the White Paper. Time, however, was of the essence of the contract, and he was not prepared to agree with Lord Addison that the techniques necessary to implement the Government policy must necessarily take a very long time. The Ministry of Agriculture would be responsible for the production of the Minister of Food for the distribution of clean milk, as to ensure that the supply of clean milk to the citizen was guaranteed.

Anomaly of "Accredited" Milk

There was, however, one exception to this general sense of satisfaction which medical men and women felt about the safeguards outlined by the Government, and that was the sale of milk from an accredited herd. He believed that much of this milk was not obtained from tuberculin-tested cows, that were so, why was it not going to be an offence to sell this milk unpasteurized? He hoped that the Government would reconsider this important point. With regard to the Ministry of Agriculture taking over the supervision of the conditions of milk production, it was to be hoped that the local authorities would not be canny in the matter of vigilance for clean milk but would still hold a watching brief for the consumer. The supply of veterinary inspectors would for some time be very limited. The efficient working of the Government's policy would require frequent sampling of milk, especially milk supplied to hospitals, schools, and canteens. That sampling should still be undertaken by local authorities, and should cover bacteriological tests as well as mere tests as to keeping properties.

He denied the statement sometimes made that the medical profession were not unanimous on this matter. There was complete unanimity in the profession on this point as there was on any question in a free country like ours, where a few folk would always take a pleasure in showing their freedom by differing from the great majority. Some three months ago an influential deputation urged on the Minister of Food the need for pasteurization of bulk milk. That deputation included representatives of the three Royal Colleges, the B.M.A., the National Association for the Prevention of Tuberculosis, the Joint Tuberculosis Council, the British Paediatric Association, and the People's League of Health. There was no difference of opinion on the importance of feeding babies with milk, but when we asked what sort of milk we should pour into babies we were faced with the anomaly to which he had referred. There was a note of drama about tuberculosis which tended to lessen the significance of other diseases which were spread by germ-laden milk. He had in mind undulant fever, septic disease processes in considerable numbers, scarlet fever, diphtheria, and typhoid. It was difficult to assess the number of these septic cases which were attributable to milk. We knew a good deal more exactly how many cases of bovine tuberculosis occurred each year, but the morbidity—i.e., the prevalence—and the mortality of these cases taken together must far outweigh those due to tuberculosis.

Long-term and Short-term Policies

There were two ways, Lord Horder said, of making milk really safe for children and young adults. We could take steps to ensure that the cows that provided the milk were free from disease, and that the processes of collection and distribution were clean and not dirty. The other way was to pasteurize the milk and so sterilize it as to make it safe for human consumption. While he favoured both the long-term

and the short-term policies, the former was not enough. It could take several decades before anything like complete cleanliness was effected at the cow end. Among other things, there was the status of the veterinary profession and the paucity of numbers. We had the best stock in the world, but we had a long way to go in the care with which we looked after that stock. We must do more to encourage intelligent men and women to enter the ranks of veterinary service.

A third alternative by which milk could be made fit for human consumption was by boiling it. This alternative could not be considered for two reasons. First, boiling milk definitely lowered its nutritive value, whereas pasteurization did not. In the second place, if they warned mothers that they must not give milk to their babies unless it was boiled, they would be stigmatizing milk and sabotaging a basic food. They would prevent thousands of mothers from giving it at all, and would lower the popularity of milk in such a way as adversely to affect its production.

In these days, with steel in short supply, pasteurizing plants could not be multiplied indefinitely, but it was not impracticable or their number to be largely increased and for milk to be bulked to a greater extent even than at present. It might not be a bad thing to release a little steel to make the pasteurizing plants. There were people who said that this must wait until after the war. It could not wait, for the position worsened rather than improved. The Minister of Food recently admitted that a lot of T.T. milk found no market as such, and the White Paper gave no assurance that this position would improve in the near future. A large quantity of T.T. milk was mixed with dirty milk. It had been said that this system of making milk safe by pasteurization was likely to drive the small producer-retailer out of business. We should all regret that, but the cover offered to the small producer-retailer by the proposals of the White Paper should disabuse people's minds of the idea of hardship inflicted on him. If the technique needed to pasteurize all bulked milk eventually resulted in the shutting down of some of the dirtier milk-handling and distributing premises, so much the better for the community.

Extent of Pasteurization

Lord WOOLTON said that already in London 96% of milk was pasteurized, in Manchester 85%, and in Glasgow 70%. In the areas of over 10,000 population—the areas with which they were dealing—65% of the milk was already in pasteurized form. Their estimate was that within the next few months they would be able to increase the amount of pasteurized milk from 65% by another 15%, and that in a year from that time—18 months from now—they would be able to cover the whole of the country in which they had introduced rationalization schemes. The problem before the Government was to get sufficient new plant to deal with this increased quantity of milk. Broadly speaking, the rationalization schemes would deal with all the places where there was bulked milk. The mixing of T.T. milk with bulked milk was a common practice before the war. He believed that only 25% of the T.T. milk found its way as such to customers. He had taken the responsibility for seeing that that milk should be marketed. His intention was to try to direct it to these centres so that children should have it; to try to direct it to consumers, so far as transport difficulties would allow, so that they might purchase it as T.T. milk; and so to direct it that it should be sold at a price which people could afford.

He had been asked by Lord Horder about accredited herds, and whether it was not true that, even within the limitations the Ministry had made, there would not be a danger of tubercle. Certainly it was true. This was another example of the best being an enemy of the good. If they had waited until they had reached agreement on perfection before issuing the White Paper, they would have had to wait still longer. The Minister of Agriculture and he took what they regarded as a common-sense and practical step. They had the agreement of the National Farmers' Union, the "small retailers" subcommittee of that union, and they had all this medical and scientific opinion. It seemed to them that it was the wise and statesmanlike course to take this basis of agreement as far as they had got it, and to proceed to act, knowing full well the mechanical hindrances to getting any further amount of milk treated. He hoped, therefore, Lord Horder would not think they had been half-hearted about this. They had adopted a political compromise which took them a long way further on the road and at any rate gave them an opportunity of doing all that they could do with the material at their disposal.

Diseases "Normally Unaffected" by War Service

Mr. DRIEBERG on July 29 asked the Minister of Pensions to circulate the list of diseases held by the current consensus of medical opinion to be neither caused nor aggravated by military

service. Sir WALTER WOMERSLEY replied that it was impossible to extract from all the diseases known to medical science a complete list of those in the causation or worsening of which war service would be unlikely to play any part. There were, however, certain diseases or groups of diseases the onset or development of which would normally be unaffected by service. It should not be assumed, however, that every case in which the disability was due to one of these diseases was necessarily rejected. Examples of the more common of these were: malignant diseases with certain well-recognized exceptions; certain diseases of the glands—for example, lymphadenoma; certain diseases of the nervous system of developmental origin—for example, syringomyelia; certain diseases of the blood and blood-forming organs, such as leukaemia; progressive visual changes due to errors of refraction; and venereal diseases.

The White Paper on Health Services

On August 3 Capt. PETER MACDONALD asked the Minister of Health when he proposed to issue his White Paper containing his preliminary proposals for implementing the health scheme of the Beveridge report. Miss HORSBRUGH said that the Minister hoped it would be possible to publish a White Paper about the time when the House reassembled. This would then serve as a focus for full discussion by all concerned, including many interests besides the medical profession, and it had always been the Minister's clear intention to give ample opportunity for this.

Food Value of Oatmeal

On August 3 Mr. MATHERS asked the Secretary of State for Scotland whether he could give any information about the effect on the nutritional and health standards of persons who made oats and other characteristic Scottish products a prominent feature of their diet. Mr. JOHNSTON said that oatmeal was a highly nutritious grain, rich in some of the essential elements of an adequate diet—namely, vitamin B₁, carbohydrates, protein, and fat. Like any other item of diet, oatmeal was not generally consumed by itself as a complete food, but as a cereal it was shown by chemical analysis to be four times as rich in fat content as white wheat flour, while oatcakes were 10 times as rich in fat content as white bread.

Replying further to Mr. Mathers, Mr. Johnston said his statement was founded on an analysis by Dr. McCance, published by the Medical Research Council.

Accommodation and Nursing for Tuberculosis in Scotland

On August 3 Mr. JOHNSTON informed Mr. McNeil that on July 1 last 1,007 patients suffering from pulmonary tuberculosis had been waiting for hospital accommodation for 10 days or more. Between the beginning of April and the beginning of August 244 new beds had been occupied, and nursing staff had been obtained for 65 additional beds which had not been in use owing to lack of staff. A further 130 beds were ready for occupation as soon as nursing staff could be obtained, and a still further 330 new beds would be available immediately certain adaptations were completed, provided there was nursing and domestic staff. Proposals to cover the remainder of the waiting list by release of further emergency hospital service beds were being urgently examined.

The Medical Student

During the debate on education in the House of Lords on August 4 Lord MORAN said that for 25 years he was dean of a London school of medicine to which every year came 60 or 70 new students, who, for the next five, six, or seven years, applied the education they had already been given to the new task of becoming doctors. The results on the whole were disconcerting. Many of these boys lacked reasoning power. Many were without curiosity. A student without curiosity was not a student at all. He would not debate how far these defects were due to early specialization, and how far to the examination system. In the education of the medical student they kept adding to the curriculum; they never took away. They asked him to memorize a mass of facts instead of teaching him how to handle them. Before they sent him away they contrived so to educate him that he could not educate himself. He had no power of growth. Lord Moran said that he himself had come to inquire not how much a man knew when he qualified, but whether he wanted to learn and if he knew how to learn. The explanation of this curious ineffectiveness was that the teaching art was of extreme difficulty. Nothing would come of Parliament's efforts in education unless it could explain to the country that it must have the best for the teaching profession, and unless they had a method of finding out during the war the men needed for the profession. Relationship between teacher and pupil was so important. One could talk to a class, but could only teach boys and girls whom one knew. That was

The Bill received the Royal Assent on August 5.

Mr. BROWN said the nursing organizations were asked to nominate to the Rushcliffe Committee and had done so. It was not due to him that there were not more women on the committee. The committee had spent 15 months going through the categories of nurses, and it was necessary that the Ministry should act swiftly on this side of the committee's work, since the Athlone Committee's report had been necessarily laid aside when war broke out. He did not bind himself, to accept what the Rushcliffe Committee might recommend on other subjects. At the moment he did not see any justification for altering the major recommendations.

Women in War

During a debate in the House of Commons on August 3 on the position of women in national service Dr. EDITH SUMMER-SKILL said that in the Women's Auxiliary Services women were now replacing men, head for head. Those who had seen the women on the A.A. gun sites had been very-impressed by their work. Yet these picked personnel on gun sites were paid only two-thirds of the men's rate. The only women in the Services paid the same rate as men were doctors, although other women were doing work which was just as specialized. There were brilliant scientists in the Services who were being paid only two-thirds the rate. The doctors had a strong organization to protect them. It should not be necessary in this country for women to be strongly organized in the Services before they could get justice. The B.M.A. would not sanction the Government recruiting women doctors at a cheap rate. Therefore women doctors, who were organized, were treated fairly, while unorganized women who had no trade union were not. She also could not understand why women members were not allowed to practise first aid in the Home Guard, and why women doctors were not eligible for service in the Home Guard.

Nurses (Scotland) Bill

The Nurses (Scotland) Bill passed through the report stage in the House of Lords on July 15 after an amendment had been made, on the motion of Lord Alness, to enable persons to be placed on the roll of assistant nurses on producing evidence that they had been engaged in practice before the passing of the Act. The Bill was read a third time on July 20 without debate and was returned to the House of Commons. The House of Commons agreed to the Lords' amendment on July 21.

On July 27 the House of Commons agreed to the Lords' amendments. Mr. THOMAS JOHNSTON said that existing facilities for the training of nurses were, by common consent, insufficient. They were 700 trained nurses and 600 assistant nurses short of requirements. The principal amendment inserted by the House of Lords and which the Government accepted made some little contribution to training facilities. There were

Working Hours of Nurses.—Sir HENRY MORRIS-JONES inquired on July 20 whether the recommendations of the Rushcliffe of a 96-hour fortnight for the general body of nurses had been adopted by voluntary and municipal hospitals in this country as a statutory obligation, and whether these hours included time for meals. Mr. BROWN replied that the Nurses Salaries Commission recommended that a 96-hour fortnight should be brought into national operation as soon as circumstances permitted, and that it was to be determined by him, having regard to the availability of nurses and subject to the requirements of the service. He could not say whether the supply of nurses at the present time sufficed to enable the 96-hour fortnight to be worked at all hospitals. The Commission made no reference to time spent at meals, but the Interdepartmental Committee, under the chairmanship of Lord Athlone, to which the recommendations of the Rushcliffe Committee were referred, drew attention to the fact that the 96-hour fortnight was meant to be exclusive of time for meals.

Raw Milk Supplies.—Major YORK inquired on July 21 in areas scheduled under the new milk scheme it would be permissible for parents who prefer raw milk for their children to obtain delivery. Mr. MADANE replied that it was not possible for themselves to obtain delivery. Their existing retailer was able to supply them with raw milk, but not otherwise in scheduled areas.

White Paper on Population.—In the House of Lords on Earl De LA WARR asked the Government when they would issue the White Paper on population, which was promised in the Budget on June 8. Lord SNELL said that the preparation of this Paper was obviously an elaborate task, and the Minister of Health regretted that he could not at present give any indication when it was likely to be completed.

Supply of Nurses.—Mr. MALCOLM MCCORQUODALE, in August 5 to Sir Ralph Glyn, said that just over 400,000 persons registered under the Nurses and Midwives (Registration for men) Order, 1943. Of these approximately 270,000 were at the time of registration in some form of nursing or midwifery work. About 130,000 were not engaged in such work. It was expected that most of these, on account of age, family responsibilities, or for some other reason, would prove not to be available for the nursing or midwifery services. Any approach to return to the nursing or midwifery services. A serious problem of satisfying the demands for nurses and midwives included the recruitment of additional persons at present in such work, the redistribution where necessary of persons performing these services, and the return to the service of experienced persons not at present practising. Interviews with persons registered recently and of those who came to the attention of the recent publicity appeal began at the Department's response to the recent publicity appeal began at the Department's offices of the Department in June. During June and July, 2,000 nursing and midwifery vacancies had been filled.

Mass-Radiography Units.—Mass radiography sets already being delivered as quickly as is compatible with other work on material and the highly skilled labour required, but expected that delivery will be completed much before the next year. In the meantime Mr. Ernest Brown will be in question of ordering further sets. He has suggested to the authorities that arrangements should be made between the sharing the use of the units now in course of allocation and the apparatus is readily transportable.

The latest revision of the list of medical reference b to all medical units at home and abroad was started this year and was completed early in July. The Directorate of Army Medical Services, is advised in these matters by the Medical Department Consultants' Committee.

The first miniature radiography unit has not yet been delivered to Glasgow Corporation but is expected to arrive almost immediately.

Under the milk-in-schools scheme milk may be supplied by persons who have been approved by the medical officer on the ground of the source and quality of their supply, with the medical officer of health to determine what other evidence he should require for this approval.

The principal British representatives in Allied Military in Occupied Territory include Colonel Gordon Cheyne, Chief Health Officer.

No. 30

EPIDEMIOLOGICAL NOTES

INFECTIOUS DISEASES AND VITAL STATISTICS

For print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 31.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) the 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Discussion of Table

In England and Wales notifications of measles were down by 224, and of whooping-cough by 185. There were also 120 fewer cases of scarlet fever (41 fewer in Middlesex): a feature of this disease during recent weeks has been the large fluctuations in alternate weeks with only very small differences in the intervening weeks. Diphtheria, notifications of which have been at a fairly constant level during the past two months, rose in incidence by 18 cases.

Within the counties there were large variations in the trend of whooping-cough. There were 60, 59, 39, and 31 fewer notifications respectively in Lancashire, Durham, Glamorganshire, and Devonshire; in Warwickshire there were 45 more cases and in Shropshire 37. Measles was down in Kent by 60 cases, in Surrey by 48, in Northamptonshire by 37, in Wiltshire by 37, and in Lincolnshire by 36: the only increase of any size was of 35 more cases in Norfolk.

Dysentery notifications were 6 fewer than in the preceding week. Small outbreaks occurred in Wiltshire 6 (Amesbury R.D. 4, Calne and Chippenham R.D. 2) and Shropshire, Oswestry R.D. 9. The infection persists in Bristol C.B., where there were 10 further cases during the week: 13 cases were reported in both London and Lancashire.

In Scotland a large rise—21 cases—in the incidence of dysentery was recorded for the third consecutive week, this being due to the increase in the County of Kincardine; where the cases went up from 15 to 60. In West Lothian County notifications dropped from 50 to 35. The incidence of dysentery remains high in the cities of Aberdeen 18 and Edinburgh 15. Only 13 cases of cerebrospinal fever were notified—about half the weekly average for the preceding two months.

In Northern Ireland the principal centre of diphtheria was in the County of Londonderry, where 15 of the total of 40 cases were recorded.

Infections due to Food

The monthly bulletin for August of the Emergency Public Health Laboratory Service describes the results of the investigations into outbreaks of food-poisoning. An outbreak of paratyphoid in Sussex was traced to infected milk. The agent was a school employee who was mainly responsible for the distribution of the milk to the children. A small outbreak of food-poisoning in Berkshire was attributed to brawn. The unhygienic method of preparing the food resulted in the introduction of *Staph. aureus* from pustular lesions on the hands and wrists of the employee engaged in the final stages of mixing the brawn. An outbreak of food-poisoning at Barnstable was also traced to infected brawn. The brawn was contaminated by a chronic nasal carrier of *Staph. aureus*, and the organisms proliferated rapidly, as the brawn was kept at room temperature overnight during the warm weather prevailing at the time. These investigations emphasize the importance of personal hygiene among the staffs preparing food and also the need for keeping prepared foods in a cool place.

The Week Ending August 7

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,520, whooping-cough 1,614, diphtheria 493, measles 1,903, acute pneumonia 484, cerebrospinal fever 34, dysentery 122, paratyphoid 5, typhoid 8.

Medical News

In the account published in the *Journal* of August 14 of the experiences of British surgeons on their visit to the U.S.S.R., we omitted to mention that Col. Elliott C. Cutler, M.C., Chief Consultant in Surgery, American Army Medical Corps, was one of the distinguished American surgeons who formed part of the joint Anglo-American Mission.

The latest step in the campaign for the prevention of blindness in India is a "floating eye hospital" which has been equipped in Bengal to travel the canals and waterways of the country.

The Homes of Recovery for War-blinded Civilians, which were established after the outbreak of war by the National Institute for the Blind to provide special training for air-raid casualties, have proved so helpful to persons losing their sight late in life that they are to be a permanent part of the Institute's work. In future they will be known as the Queen Elizabeth Homes of Recovery. One of them was presented to the Institute by the British War Relief Society of America.

The Ministry of Health announces (Circular 2843) that as from April 1 last the pay of members of the Civil Nursing Reserve is to be as follows: trained nurses in charge of a ward, £140, rising by £10 to £190; other trained nurses, £110, rising by £5 to £140; assistant nurses, £75, rising by £5 to £95; and nursing auxiliaries, £57 10s., rising by £2 10s. to £65. When the nurses are non-resident living-out allowances (in addition to meals on duty and laundry) of £70 for a trained nurse in charge of a ward, £65 to other trained nurses and assistant nurses, and £55 to auxiliaries should be paid. All members of the reserve who are employed in a tuberculosis institution or tuberculosis wards should receive an additional £10 a year and free travel twice a week to the nearest centre of population. The circular, which has been sent to local authorities, voluntary hospitals, and local emergency organizations, also sets out the conditions governing annual and sick leave.

The Minister of Health, addressing the annual conference in London of the National Association for the Prevention of Tuberculosis, said that in 1942, the third year of war, the number of deaths from tuberculosis fell to the record low level of 1938, the last year of peace. The total was less than half the number of deaths in 1918. But the tuberculosis death roll was an index of past rather than present conditions, and the circumstances of war must favour the spread of the disease. It was for this reason that the Government decided to intensify the attack on pulmonary tuberculosis immediately by "opening two new fronts"—mass miniature x-ray photography and special allowances while under treatment for people with dependants. It was estimated that when this scheme of allowances was in full swing the cost to the Exchequer would be about £3,000,000 a year. "In the past," the Minister said, "fear of having to resort to poor relief made many a sufferer go on working until hope of effective treatment faded or disappeared. The new scheme of allowances is not a system of doles or pension, but a weapon put into the hand of the doctor in his fight against tuberculosis, at a stage when he has every chance of beating his enemy."

The Home Service Ambulance Committee of the Order of St. John and British Red Cross Society suggests that, to conserve petrol and tyres, doctors who want patients brought more than forty miles to London should make use of the committee's ambulances which otherwise would return empty to London. Notice by letter two days before the date of the journey should be sent to the Joint Secretaries, Home Service Ambulance Committee, 12, Grosvenor Crescent, S.W.1.

Dr. J. Rawdon Soddy, Colonial Medical Service, is reported missing at sea.

The Services

Cols. (Temp.) A. Bremner, M.C., T.D., D. G. Cheyne, O.B.E., M.C., and E. E. S. Wheatley, D.F.C., R.A.M.C., have been appointed C.B.E. (Military Division) in recognition of gallant and distinguished services in Tunisia.

Lieut.-Col. B. P. Baliga and Major (Temp. Lieut.-Col.) A. Ullah, I.M.S., have been appointed O.B.E. (Military Division) and Capt. (Temp. Majors) J. Hay-Arthur and W. J. F. Young, I.M.S., and Jemadar S. Y. Bhagwat and Asst. Surg. 1st Class L. H. Carr, I.M.D., have been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services in Persia-Iraq.

The following have been mentioned in recognition of gallant and distinguished services in Persia-Iraq: Major-Gen. (Acting) J. G. Gill, D.S.O., O.B.E., M.C., and Brig. (Temp.) C. D. K. Seaver, late R.A.M.C.; Cols. (Temp.) W. M. Cameron, O.B.E., J. J. Magner, M.C., T. H. Sarsfield, and C. Scales, M.C., R.A.M.C.; Lieut.-Col. L. B. Clarke and Majors (Temp. Lieut.-Cols.) W. A. D. Drummond, P. J. Richards, and T. Seager, R.A.M.C.; Capt. (Temp. Major) D. J. Wigginton and Capt. G. A. C. Miller and W. C. Wightman, R.A.M.C.; Col. (Temp.) K. S. Master, M.C., I.M.S.; Majors (Temp. Lieut.-Cols.) B. J. Griffiths and F. C. Jackson, I.M.S.; Majors R. L. Henderson, L. Oswald, and J. R. Vaid, I.M.S.; Capt. (Temp. Majors) R. M. McCullough, F. J. O'Dowd, and J. H. Walters, I.M.S.; Capt. B. Ahmed, S. P. Bhalla, A. Hag, N. A. Curashy, S. P. Mukherjee, and S. A. Sheikh, I.M.S.; Subadar-Major B. Ram, I.M.D.; Subadars K. R. Channa, G. C. Pahawal, and S. Ram, and Jemadars J. Subrahmanyam and M. S. Kataria, I.M.D.

CASUALTIES IN THE MEDICAL SERVICES

Wounded.—War Subs. Capt. D. M. Cathie, R.A.M.C.

Prisoners of War.—Major H. J. Anderson, R.A.M.C., Capt. W. R. Grant, R.A.M.C., War Subs. Capt. J. F. Pantridge, R.A.M.C., Major J. A. Reid, R.A.M.C., War Subs. Capt. A. Roy, R.A.M.C.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (9.15 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Atology Westcent*, London; SECRETARY, *Medisera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Intermittent Claudication

Q.—I should be grateful for any information that you can give me that is likely to benefit the following case. A male patient of 70 years, who has cramp-like pains, more particularly in the leg, thigh and calf muscles, is prevented from walking more than a few hundred yards. As he is a farmer this is naturally a great handicap. On examination he is rather a thin subject with no undue amount of arteriosclerosis. His B.P. is normal for his age, and his urine is free from albumin or sugar. Rectal examination shows a slight prostatic hypertrophy but no other abnormality. I presume the condition is one of intermittent claudication, but am at a loss to attribute a cause.

A.—Yes, this is an example of intermittent claudication, and it is due to arteriosclerotic changes in the arteries to the lower limbs. With such aetiology this occasional accompaniment of age has to be regarded as beyond the power of a doctor to alter in any effective way. If so, the indication is to dwell on the favourable signs and absence of complications noted in your patient, and to prevent him from becoming too much preoccupied with his disability. He must accept it and make all possible arrangements to avoid unnecessary walking—a plan which will be easier when more petrol is available after the war. Warm clothing is needed, and scrupulous care and cleanliness of the skin, so as to avoid the least injury to the legs; that have a restricted blood supply and might not heal readily.

Pillows

Q.—Are pillows necessary or advisable for the nursing of infants and children with respiratory illnesses such as pneumonia and whooping-cough? Do healthy children up to the age of 5 need pillows?

A.—This question of pillows seems to be a matter of common sense. Some nursing books recommend that patients with lobar pneumonia be nursed sitting up and with bronchopneumonia lying down, but it has always seemed to me at any age the best position is the one in which it is found that breathing is most efficient and comfortable and in which sleep is most easily secured. The good nurse uses pillows by a process of trial and error to secure these aims. It is impossible to lay down rules for every type of child and illness. Custom plays a part which leads to the second question. Usually a baby has a small pillow and most young children prefer a low pillow. But it is probably immaterial whether a child has one, two, or no pillows so long as sleep is calm and peaceful. Adults vary with their likes and dislikes as regards pillows, and with children it is the same. But the danger of mastoid infection from feeding young children in the recumbent position, and of allowing them to remain lying too long in one position, should be remembered (see article by Mr. P. W. Leathart in the *Journal* of August 7, p. 168).

Aschheim-Zondek Test

Q.—What reliance can be placed on the Aschheim-Zondek test for pregnancy in the early stages—say after two weeks' amenorrhoea? Can a negative result at this stage be accepted as a definite proof of absence of pregnancy?

A.—The Aschheim-Zondek test is to be regarded as a test for the presence of live and active chorionic tissue in contact with the maternal circulation rather than for pregnancy. As such it is accurate in 95 to 97% of cases, and there are more false negative than false positive reactions. In pregnancy the test usually becomes positive within one week of a period being missed, but this is by no means constant, and a negative reaction after two weeks'

menorrhoea should not be accepted as definite proof of the absence of a live pregnancy. If clinical signs of pregnancy persist the test should be repeated after an interval of one week. All reactions, and particularly "doubtful" ones, require careful interpretation, bearing in mind the clinical features of each case.

Vitamin C Saturation Test

Q.—Will you kindly inform me of the exact amount of ascorbic acid required to saturate the blood in order to do the urine ascorbic acid saturation test. Does the amount required vary with different age levels?

A.—There is a "saturation test" in which ascorbic acid is estimated in the urine after the oral and parenteral administration of a test dose of ascorbic acid. Like glucose and some other compounds, ascorbic acid is a threshold substance, with a critical level of excretion at about 1.4 mg. per 100 c.c.m. of blood plasma.

The rationale of the saturation test is based on the hypothesis that after the administration of ascorbic acid the requirements of the tissues for the vitamin are satisfied before the concentration of ascorbic acid in the blood rises to the threshold value and is eliminated in the urine. For practical purposes the method of Larriss (*Lancet*, 1937, 2, 1429) may be used. At 9 a.m. the individual empties the bladder and the specimen is rejected. Another specimen is obtained at 12 noon and titrated with 2,6-dichlorophenolindophenol solution for ascorbic acid; any urine passed during the three hours is also collected and titrated. This procedure is repeated on a second and third day. After this, for one or two further days, or more if necessary, a test dose of 70 mg. of ascorbic acid per stone of body weight is given orally in 100 c.c.m. water at 10 a.m. and the urine collected on the same day between 2 and 5 p.m. This two or three hours' afternoon specimen reveals if there has been an increased excretion of ascorbic acid in response to the day's test dose. The test is repeated daily until a sharp rise in the urinary excretion of ascorbic acid is obtained: 5 to 50 mg. per stone of body weight shows a sharp rise in the urinary excretion of ascorbic acid on the first or second day of testing. With increasing deficiency there will be an increased number of days' delay before a response is obtained. The amount of the test dose depends on body weight rather than on age. It is 70 mg. per kilo of body weight. For further literature consult *Lancet*, 1940, 2, 259; 1942, 1, 265, 642, 644, 647; and *British Medical Journal*, 1940, 2, 217.

Injection of Fibrous Nodules

Q.—What is the technique of injection of novocain or similar drug for relief of severe pain from fibrositic nodules in region of shoulder girdle? Can permanent relief be attained by this method? The condition is now subacute and the pain comes on in attacks.

A.—Injection of fibrous nodules and indurated regions is regarded as extremely valuable in the treatment of fibrositis. The nodule is recognized by its tough consistency, and pain is felt on penetration. It is infiltrated with 5 to 15 c.c.m. of a 1/2% solution of procaine in saline, which should be delivered in the centre of the nodule. Infiltration abolishes the pain, and if this does not happen it is probable that the nodule has not been properly located. To obtain the maximum benefit, injection should be followed immediately by massage and stretching of the affected muscles. Successful injection is usually followed by permanent relief of pain, but there may be recurrence as a result of incomplete disintegration of the nodule or the formation of new nodules. The injection should then be repeated. In assessing the results of physical treatment it should be remembered that there is an increasing tendency to incriminate psychogenic factors in cases of fibrositis which do not respond readily to treatment.

Painful Legs in Elderly Diabetic

Q.—A woman aged 67, well in every way except that she has mild diabetes mellitus, controlled by 5 units of ordinary insulin a day—blood pressure 160/90—complains only of great pain in her legs on walking other than a little distance. X-ray examination shows the femoral and tibial arteries to be more or less continuously calcified, and the course of both arteries can be followed in the skiagrams down both legs by the calcification of the vessels. I have no doubt of the diagnosis but am at a loss for any treatment. I feel massage is contraindicated and have my doubts about using acetylcholine. Should be grateful for any help.

A.—As the diabetes is controlled by such a small daily dose of insulin, it is improbable that the arteriosclerosis is diabetic in origin. It is presumably a senile degenerative lesion. The pain in the legs on walking is due to insufficient blood supply to the muscles. The only hope of improvement lies in attempts directed to increase the blood supply through arteries which are not calcified. For this purpose the patient should sit in a hot bath for half an hour daily. Massage to the legs twice a week has proved helpful in some cases. It would also be worth while trying the effect of giving by mouth nicotinic acid 50 mg. t.d.s. Acetylcholine is

not likely to be helpful. If the patient is on a low-carbohydrate diet it would be well to increase the carbohydrate, and the insulin too if necessary, with the idea of preventing any diabetic arterio-sclerotic changes from occurring.

China Root

Q.—Dr. E. Ashworth Underwood, in his interesting article on the "Fabrica" of Vesalius, mentions the "China root" which Vesalius used in 1537 for treatment and made the subject of a "letter" in 1546. What was this root? "Chambers's Encyclopaedia" (about 1886) mentions the letter but does not explain its subject. The "Encyclopaedia Britannica," latest edition, has not even an article on Vesalius.

A.—China root—*Radix chinensis*—is supposed to be the root of *Smilax china* L., a native of Japan and Eastern Asia. *S. glabra* Roxb. and other varieties furnish similar roots. China root was used in the same way as sarsaparilla, which belongs to the same genus, *Smilax*. In the East it has a very ancient history. In Europe it was probably first mentioned by Valerius Cordus (1515-44), and its use as a remedy for syphilis was made known to the Portuguese by Chinese traders about 1535. The Emperor Charles V was reported to have been much relieved of his gout by its use, and this success prompted several works, the earliest of which is the *Epistola* of Vesalius. It continued to be used as a sudorific and alterative until the beginning of the eighteenth century, and even in the second half of the nineteenth century it was still to be found in some pharmacopoeias.

The Letter of Vesalius is important not because of the description of the therapeutic use of the root but on account of the valuable autobiographical notes which it contains.

Endocrine Factor in Migraine

Q.—I have under my care a very severe case of migraine in a male aged 30, which has failed to respond to the ordinary analgesics, ergometrine, fémérin (ergotamine tartrate), or the antitriptin S treatment. I would be grateful for any suggestions in the treatment of this case.

Q.—I should be grateful for information about the use of A.P.L. hormone in the treatment of obstinate migraine. The patient is a married woman aged 42, who has had the attacks for eight years at least. She has had a great deal of treatment from various consultants without avail. She has not had this hormone. She is temporarily relieved by fémérin. The attacks are frequent and incapacitating, and seem to have no relation to menstruation.

A.—In both these questions the use of gonadotrophic preparations is mentioned. The scanty available evidence indicates that migraine of endocrine origin is probably due to over-activity of the anterior pituitary. For instance, excess of gonadotrophin and deficiency of oestrogen have been found in the urine of women suffering from "menstrual migraine." Again, the timing of these attacks to the immediate premenstrual and menstrual phase of the cycle, when oestrogen secretion is low and gonadotrophic activity (especially of the follicle-stimulating type) is high, is suggestive. Furthermore, migraine sometimes appears for the first time at the menopause, when follicle-stimulating gonadotrophic activity is increased. Claims have been made for the relief of migraine by administration of either oestrogen or androgen, presumably by depressing pituitary gonadotrophic activity. Finally, administration of gonadotrophins has been found to aggravate the attacks and even to induce migraine in women showing a low oestrogen, high gonadotrophin urinary balance.

The possible aetiological factors, however, are many. Cases are reported as being associated with low B.M.R.s and signs of hypothyroidism. On the other hand the combination of Graves's disease and migraine in which both conditions were relieved by thyroidectomy is recorded. Dilatation of the cerebral or cranial vessels, which can be produced by histamine or counteracted by adrenaline or ergotamine tartrate, may be the cause in some cases. Some are allergic in nature and may be treated in accordance with the findings of skin tests. In other cases errors of refraction or nasal congestion may precipitate attacks.

Fuchsin Paint

Q.—What is the composition of Castellani's fuchsin paint? What is its main use apart from epidermophytosis?

A.—Castellani's fuchsin paint consists of: saturated alcohol solution of basic fuchsin, 10 c.c.m.; 5% aqueous carbolic solution, 100 c.c.m. Mix, filter, and add boric acid, 1 g. After two hours add 5 c.c.m. acetone, and shake. Two hours later add resorcin, 10 g. Mix, and dispense in dark glass-stoppered bottle. This paint is often useful in mycotic infections affecting skin folds, such as between the toes and between the fingers, and although it has been used mainly in epidermophytosis it has proved useful in the extensive ringworms of tropical origin and in yeast infections also. It may be of service in chronic pyogenic intertrigo.

INCOME TAX

Successive Appointments

S. O. held three successive appointments during 1941-2 and joined the R.A.M.C. in Dec., 1942. He married in 1941-2 and his wife also had earned income in that and the following years. Various sums of tax have been deducted by the different employing authorities. What should he do to "clear up the muddle"?

** The total tax payable for 1941-2 and 1942-3 is as follows:

1941-2.	Earnings of self	£326	
Deduct.	Earned income allowance	£33	
	Expenses	£1	
	Personal allowance	£140	
			£174
			£152
	Tax at 6s. 6d. in the £	£49 8 0	
Deduct.	Life assurance relief (£12 at 3s. 6d.)	£2 2 0	
			£47 6 0
(The wife's income is less than the allowances due to her, and no tax is payable thereon.)			
1942-3.	Civil earnings	£210	
	R.A.M.C. pay	£127	
			£337
Deduct.	Earned income allowance	£33	
	Expenses (uniform allowance)	£10	
	Personal allowance	£140	
			£183
			£154
	Tax at 6s. 6d. in the £	£50 1 0	
Deduct.	Life assurance relief (£12 at 3s. 6d.)	£2 2 0	
			£47 19 0

The wife's liability is £217, less £80 (special earned income allowance) and £22 (ordinary earned income allowance)—i.e., £115, of which (£165-£154=) £11 is chargeable at 6s. 6d. and the balance of £104 at 10s. in the £; her total liability is therefore £3 11s. 6d. plus £52=£53 11s. 6d.

As S. O. will make his future returns to the War Office, his best course will be to deal with the branch of the Inland Revenue Department which handles that side of income-tax work, and communications should be sent to the Chief Inspector of Taxes, the Hydro, Llandudno, North Wales. We suggest that S. O. send a statement of his liability on some such lines as are indicated above to that office, together with a statement setting out what deductions of tax have been made—so far as can be stated—and ask for the whole position to be cleared up and a statement supplied showing the adjustments which have been made to rectify the original charges.

Subscriptions to B.M.A. and Medical Defence Union

"ASSISTANT" inquires whether these are allowable.

** An assistant is in employment and is therefore assessable under Schedule E. The rule accordingly is that such subscriptions can be regarded as allowable expenses only when membership of the organizations, etc., to which they are paid is a condition in the terms of service of the appointment he holds.

LETTERS, NOTES, ETC.

Perforated Gastric Ulcer in Adolescent

Dr. M. AUDERIAH CONYNGHAM (Monkstown, Co. Dublin) writes: Dr. David Kyle, reporting a case of a perforated gastric ulcer in a boy of 19 (March 20, p. 370), expressed an interest in any similar records. While I was house-surgeon at the Staffordshire General Infirmary, Stafford, a collier aged 17 was admitted on Sept. 25, 1941, as an acute abdomen with a short history of abdominal pain, having previously enjoyed good health. In this case, with a pre-operative diagnosis of a perforated gastric ulcer and the kind permission and help of Mr. Roy Sworn, I performed the repair of a small acute perforated ulcer on the anterior aspect of the stomach, close to the pylorus. This was quite accessible and easily repaired. The boy made an uneventful recovery.

Continuing Research on Cancer

Surg. Lieut. EDWARD F. HUNT, R.N.V.R., writes: With reference to the editorial article on continuing research on cancer (Jan. 16, p. 79), reviewing the work of the British Empire Cancer Campaign, I was extremely interested in the experiments on the breast-feeding of cancerous strains of mice. However, one is left with the feeling that the research workers on this line of investigation have been persuaded that there must be a positive carcinogen present in the high-breast-cancer strain of mice. Personally I do not believe the experiment was carried far enough. In my opinion (as put forward in previous letters to the *Journal*) one of the main factors in the formation of cancerous growths is a negative or minus factor. In other words, in a great proportion of cancers the deciding factor is a deficiency of cancer-preventing substance. Now, if in these mouse experiments it had been possible for two further groups of mice to have been suckled alternately day by day, first by the high-breast-

cancer mother and then by the low-breast-cancer mother, it might have been found that all the babies lived to be low-breast-cancer mice. If this result occurred I feel that it might prove the milk of the low-breast-cancer mice contained an anti-cancer factor, and, vice versa, the high-breast-cancer mice were hereditarily deficient in this substance. If, on the other hand, a greater percentage of the babies produced cancer, then perhaps it could be maintained that a definite positive cancer-producing substance is present in high-breast-cancer mice. I believe this last to be quite unlikely. The Glasgow Cancer Research tends to show how vitamin deficiency can produce cancer. My own theory is based on the hyperplasia of the bone marrow in pernicious anaemia patients, which, as everyone now knows, is a deficiency disease.

Treatment of Chilblains

Dr. W. N. GRASS (West Bromwich) writes: I have found the following mixture a most satisfactory prophylactic in the treatment of chilblains: pot. bicarb. gr. 15, sod. sulphat. gr. 10, ext. colchici liq. m 5, aq. menth. pip. ad 1/2 oz. The mixture should be taken every 4 hours on the first appearance of the chilblains, or at the onset of frosty weather. It will be found that the lesions gradually subside and disappear in 5 to 9 days. The treatment can then be discontinued, but should be restarted on the first sign of any tingling or swelling which indicates the onset of another crop of chilblains. I cannot give any explanation of why this treatment should be so efficacious, but possibly there is a chemical similarity between ext. colchici liq. and nicotinic acid. The latter, I understand, facilitates the action of vitamins A and D.

A Shorter Perineorrhaphy Needle

Dr. M. H. ELLIOTT writes: Would it be correct to suggest that while the perineorrhaphy needle is not a popular instrument after our student days, it is not either a particularly efficient one; and that this may be due to the fact that the long and unwieldy handle is awkward? The suggestion is that a decrease in the length of the flat-bladed portion and also of the tubular portion by half of the handle would render it more easily used. While parturition is well tolerated, in some cases stitching is an extra burden, and it is true that the doctor is often called for this alone, with or without anaesthesia administration. The junction of the straight and curved portions should make for an efficient instrument.

Improvised Wheeled Stretchers

Major S. T. BEGGS, R.A.M.C. (ret.), writes: In reference to the notes on a wheeled stretcher in the *Journals* of May 1 (p. 542) and June 12 (p. 746), at the beginning of the war I improvised wheeled stretchers by using discarded pram wheels with the springs attached and fixing a boarded shelving by means of bolts and nuts to the ends of the springs. Straps are bolted to the boards to secure the regulation stretcher. The stretcher is released if and when required by undoing the straps. This contrivance will be found quite serviceable.

Sterility and Contraception

Mrs. MARIE C. STOPES, D.Sc., writes: In your issue of June 19 Mr. V. B. Green-Armytage says it is "remarkable that the president of the Family Planning Association should advocate the study of sterility in clinics hitherto used for birth control." The only remarkable thing in that is that they have taken so many years to imitate what I originated when I founded the first birth control clinic. I announced this in the great Queen's Hall meeting in 1921, and it has been the consistent policy of the mothers' clinics ever since that the true control of conception is that which prevents undesirable births, spaces (so that the mother can breast-feed) desirable births, and induces desired births where sterility has previously been undesired. From 1921 assistance in undesired sterility has been a feature in all my mothers' clinics.

Treatment of Whooping-cough

Dr. G. ARBOUR STEPHENS (Swansea) writes: In connexion with Dr. Richard Baker's article on whooping-cough (May 8, p. 562), I enclose a copy of an article I wrote about 40 years ago on the same subject, and as the treatment therein recommended was attended by very good results some readers may care to give it a trial. In nearly all cases one finds that the auditory meatus is hypersensitive owing to some irritation of the auditory branch of the vagus nerve. By applying a 5 to 10% solution of cocaine in glycerin and water once or twice a day to the drums and meati one is able to reduce the sensitiveness of that branch and at the same time reduce the effect of any irritation on the ends of that branch. This treatment is sometimes a relief in asthma, a disease wherein the hypersensitiveness of the drums and meati is particularly marked.

A Correction

We are asked to state that "Anaesthesin" is the trade mark of Bayer Products Limited for their brand of benzocaine. It was wrongly described as "pulv. anaesthesia (May & Baker)" in our issue of July 31 (p. 148), in the letter signed "Medical."

SURGICAL TREATMENT OF BRONCHIAL CARCINOMA

BY

R. C. BROCK, M.S., F.R.C.S.

*Surgeon to Guy's Hospital; Assistant Surgeon to the Brompton Hospital**

Less than a generation ago primary cancer of the lung was thought to be a rare curiosity; to-day it is recognized as a common condition, and ranks next to cancer of the colon in frequency in men. I see an average of some 75 new cases each year. In spite of this high incidence the diagnosis is often overlooked for many months—frequently until death is imminent. The problem of diagnosis is a large one, and cannot be dealt with fully here, but certain aspects that impress one as important demand comment.

First and foremost we must, as a profession, become more "carcinoma-minded" in regard to the lungs. We are carcinoma-minded in regard to the breast, and so is the general public. We are less so in the case of the abdominal viscera, but far more so than in the case of the lungs. Malignant disease of an abdominal organ should be thought of whenever there is any disturbance of function or even awareness of the presence of any particular viscous. This, and no more, should give rise to suspicion, and calls for investigations that will lead to early identification of malignant disease or to its reasonable exclusion. The same is true of the lungs. The first signs or symptoms of bronchial carcinoma consist of *any change from normality*, and the commonest of these is cough. This is usually dry and unproductive, and is often dismissed as "smoker's cough," "bronchial catarrh," or some such vague condition. When an alarming symptom such as haemoptysis compels attention the story may be obtained of this premonitory cough extending back over many months but treated symptomatically or not at all.

By far the most important group of symptoms arises from the infection that sooner or later follows upon bronchial obstruction; this may affect the whole lung, a lobe, or only a segment of a lobe. It often begins as an apparently straightforward attack of pneumonia or "influenza," but significantly resolves incompletely or not at all. "Delayed resolution," "unresolved pneumonia," recurrent or smouldering sepsis in part of a lung, particularly in a patient of middle age, should always give rise to a strong suspicion of malignant disease. The attack of pneumonia that ushers in the illness of a bronchial carcinoma may be followed by an empyema which is drained in the ordinary way. Since the empyema is due to infection in the obstructed bronchial tree, which is now able to drain only peripherally, healing does not occur, and a chronic empyema follows; further operations may be performed in an attempt to secure healing. I find that every year I see some half-dozen cases of empyema of this type in which the real diagnosis has been quite unsuspected.

General deterioration of health, loss of weight, and loss of strength should not be regarded as signs of carcinoma of the lung if the patient is to be successfully treated. They are

usually the signs of approaching death, and so far as operability is concerned their presence almost always means that the case is unsuitable. If at the first glance the patient is seen to be ill, wasted, toxic, or distressed, then it is my experience that little can be done. Surprise is often expressed that a diagnosis of carcinoma of the lung has been made when the patient looks so well; only too often the fell possibility has been overlooked because of this apparent well-being. If we are to diagnose this grave and fatal condition in a reasonably curable phase it *must* be remembered that the slightest departure from normality in the lungs and bronchi is suspicious and needs pursuing. It is true that the operability of carcinoma of the lung is low—rather less than 10%—and a case missed until the condition is too far advanced to treat may be of little moment in a series of figures. That one missed case may, however, cover a considerable personal or family tragedy which, with good fortune and medical alertness, might have been avoided.

Once the presence of a growth of the lung is suspected careful clinical examination must follow, but reliance upon this alone is apt to lead astray. Physical signs may be absent or equivocal, and our first dependence must be on good radiographs of the chest, lateral as well as postero-anterior. Any suspicious shadow revealed will demand further investigation by bronchoscopy, especially when the diagnosis of "unresolved pneumonia" has been suggested. Bronchoscopy should precede a bronchogram, which is then often found to be unnecessary if the growth can actually be seen and a piece removed for biopsy.

Treatment

In the present state of our knowledge the only way to achieve cure of a bronchial carcinoma is by operation. Deep x rays are of value, and may produce striking temporary recession of the growth and relief of distressing symptoms. On the whole the results are disappointing and life is but rarely prolonged, which is not surprising in view of the advanced state of the disease and the associated sepsis that is so often present when the patient is sent for treatment: in many cases death is actually hastened. Local treatment by radium or radon is also disappointing and certainly never curative. It may cause striking improvement by recanalizing the obstructed bronchus and allowing infected material to drain (Brock and Cann, 1938), but just as often it is followed by a rapidly progressive increase in the infection, leading to fatal pneumonia or massive haemoptysis.

Surgery alone holds out the hope of permanent cure to the sufferer from bronchial carcinoma, and the correct operation is removal of the whole lung by dissection of the main vessels and bronchus and of the adjacent mediastinal lymphatic glands. This procedure is in accordance with the sound surgical principles followed in the treatment of malignant disease of other organs, such as the breast and colon. Treatment by lobectomy is

* Based on a paper read before the Medical Society of London on March 15, 1943.

but rarely possible technically owing to the nearness of most growths to the hilum, and is undesirable on general grounds as the removal is necessarily incomplete. In practice the recurrence rate after lobectomy is unduly high—much higher than after pneumonectomy. It is an operation that may be indicated at times in an elderly patient with a peripherally situated growth for whom pneumonectomy would seem to be too great a risk.

Lest it be thought that dissection pneumonectomy is a drastic operation to propose it should be remembered that bronchial carcinoma itself is no gentle process, but is a severe and drastic disease. The operation is actually very well borne by the patient and is fully justified by the results. It was first performed successfully by Graham in 1933, the patient being a physician who was still alive and engaged in active practice up to one year ago and, so far as I know, still is.

Although many reports of series of cases, both large and small, have been published from America, no large series has to the best of my knowledge yet been published from this country. A few cases have been recorded in English journals (e.g., Allison and Stanbury, 1938), but it is high time that a more comprehensive report of experiences with the operation appeared for critical assessment. One of the objects of this paper is to present such a series.

One finds that those seeking information about pneumonectomy for bronchial carcinoma usually want to know four things: (1) How often can the operation be performed? (2) What is the mortality? (3) How long may the patient be expected to survive? (4) How much can he do afterwards? I propose to present my own series of cases and experiences so as to answer these four questions.

1. Operability

The operability appears to vary with different surgeons, but this is probably due largely to the type of patient being seen. For instance, the operability rate is rather higher in patients of better class than in the middle-aged or elderly poor. Moreover, a surgeon who receives his cases principally from a physician will have a higher operability rate than one who sees a larger number of cases first-hand, for the preliminary examination by the physician will lead to many being rejected at once. The operability rate of the surgeon who sees all types of patients will be much lower, much gloomier, but will be more accurate for the disease as a whole.

In 1938 I published an analysis of 106 consecutive cases seen over a period of 15 months, and in only 13 of these was exploratory thoracotomy considered worth doing, the remainder being unsuitable on account of age, poor general condition, or the extent of the growth. Of these 13, four refused operation, and of the remaining 9 who consented five were inoperable; in only four could the growth be removed.

I have kept records of another series of consecutive cases seen during the last 2½ years (since Jan., 1941), and the figures are as follows:

Total number of cases seen	187
Thoracotomy advised	37
" refused	4
" accepted	33 (18%)
Operable by pneumonectomy 14	
" lobectomy 1	15 (8%)
Died from operation	2
Inoperable at thoracotomy	18
Total inoperable	172 (92%)

be seen that the incidence of operable cases is but higher than in the earlier series, and is still only 8%. figures may be compared with those published by

Overholt (1940) of Boston, whose findings were as follows:

Total cases	104
Thoracotomy advised	52 (50%)
Pneumonectomy 17	
Lobectomy 4	21 (20%)
Died	7
Total inoperable	83 (80%)

This series represents Overholt's experience over a period of six years, and at first sight it would seem that he has shown the condition to be much more favourable than appears from my own series. I think the explanation lies in the fact that many of his cases were selected before being referred for consideration of operation. This is supported by the fact that

over a period of nine years I have performed exploratory thoracotomy on 65 cases, of which 29, or rather less than half, were found to be operable. This agrees closely with Overholt's findings at operation, and suggests that the apparent discrepancy lies in the grand total of all cases seen by him being relatively rather small. Whereas he has seen 104 cases over a period of six years, I estimate that I have seen a total of some 450 cases over a period of nine years.

The conclusion, therefore, is that, taking cases of bronchial carcinoma as a whole, rather less than 20% are considered to be favourable enough to justify exploratory thoracotomy, and in rather less than half of these will the growth be found operable. The actual operability rate is at present approximately 8%. It is hoped that this figure will be improved upon with earlier diagnosis, but the condition even then would still remain one of the utmost gravity.

2. Mortality

Since the number of cases found operable in this series is relatively small it is clear that no hard-and-fast conclusions can be drawn; it is only possible to present the figures as they now stand and to draw what conclusions one can. The small number of cases is also rather disproportionately and adversely affected by the higher mortality that necessarily occurred in the early days, when the operation was less well understood. Thus I was unfortunate in losing, for one reason or another, my first four pneumonectomies—a bad start which has needed much making up. The present position is:

Total cases found operable	29 (3 lobectomy)
Died from operation	8
Died from recurrence	7
Alive and well	14

The operative mortality of 29% given by these figures is undoubtedly exaggerated. As already mentioned, four of the deaths occurred in the first four patients submitted to pneumonectomy, at least two of which would have been avoided to-day. Again, of the 8 deaths four were in patients over 60. I have had only one patient over 60 survive; he was a man of 63 who underwent lobectomy and not pneumonectomy, and is still alive and working 2½ years after. Out of 70 successful cases collected from the literature by Overholt (1940) only 6 were in patients over 60 years of age. It would thus appear that the operation carries a much higher mortality in these older patients.

The four deaths from operation since the first four consecutive deaths occurred in patients aged 64, 65, 64, and 46; the last of these had a large growth and was a poor risk: he died three weeks after operation from an abscess in the remaining lung. With the exception of this man all the patients under 60 since the first four fatal cases have survived operation. The mortality should also be considered in connexion with a series of 14 cases in which I have performed pneumonectomy 10 times and lobectomy 4 times for the condition of so-called bronchial adenoma, with only two deaths. Although the tumour in these cases was not frankly malignant these patients are usually just as bad operative risks as those with frank carcinoma.

One is therefore justified in postulating that pneumonectomy performed properly for carcinoma in a patient under the age of 60 should not carry a high operative risk—certainly not much more than 10%.

3. Recurrence Rate

It is next necessary to consider the prospect of freedom from recurrence that awaits those patients who survive the operation for removal of their growth. Here again the smallness of the numbers introduces an element of error, which is also aggravated by the relatively short time that has elapsed since operation in many of the survivors. In any case, the problem is a complex one and dependent in great part on the type of growth with which one is dealing. For instance, a young patient with an anaplastic carcinoma has a poor expectation of life, however early the growth is removed. A patient in the fifties with a small well-differentiated squamous-celled growth can reasonably expect long survival or even cure. Graham's first successful case, it should be remembered, has certainly enjoyed at least nine years of freedom from recurrence, and this patient is probably still alive, more than ten

years after. There are as yet only a few records in the literature of cases followed up for as long as five years, but enough exist to show that for shorter periods the prognosis compares favourably with that of the surgery of cancer of most other organs. It should be remembered that, although occasional untreated patients may live for as long as one or two years, the average expectation of life is generally accepted as being about six months.

The results in my own 21 survivors of operation are as follows:

Patients still alive and well after operation (14):

After 4½ years	1
" 3½	2
" 2½	3
" 1½	2
" 1 year or less	5

Deaths from recurrence (7):

Lived 2½ years	1
" 1½	1
" 9 months	2
" 2	2

The two patients who died from recurrence two months after operation had soft, rapidly growing, poorly differentiated tumours. There is little doubt that if this type can definitely be recognized without operation it should be submitted to deep x-ray therapy in preference to pneumonectomy.

4. How Much can the Patient do After Successful Pneumonectomy?

Providing the patient has survived operation and is free from recurrence, what disability is he to expect from his pneumonectomy? The answer is that disability is negligible or absent in almost all cases. A small proportion may be left with a discharging sinus, but with modern methods this should not happen often. Of my own 21 patients who survived operation sound healing occurred in all but one, which is a recent case still undergoing treatment. Only one patient needed a thoracoplasty; the rest healed by primary intention or after a short period of drainage, and with *no deformity*. Every one of the survivors has been able to return to his former occupation or to one of a similar type. These occupations include hard manual work for long hours. For instance, one patient is able to work a 14-hour shift and does heavy digging in his garden and on his allotment; another is a motor mechanic; a third a butcher working a full day and lifting heavy loads; yet another is a London taxi-driver. It is impossible, when watching these patients working or walking about, to detect any disability or abnormality. Although a few may complain of some dyspnoea on hurrying or climbing stairs for the first few months after operation, this soon passes off, and all ordinary things can be done with no sign of distress at all. One patient recently drove himself 550 miles in two days without fatigue.

Even in those patients who succumb to recurrence the operation is usually well worth while, since by the removal of the obstructed and infected lobe or lung they lose their toxæmia, fever, and sputum, and are able to carry on normally almost until the end.

Conclusion

Although bronchial carcinoma remains a terrible and fatal disease in by far the greater proportion of cases, the outlook has been improved in that, whereas a few years ago the diagnosis was synonymous with a death warrant, to-day rather less than one patient in ten has a good chance of survival if submitted to early radical operation. Of those who survive operation a number will be cured, a number will have their life prolonged, and all can expect to continue to earn their living in comfort and without disability. Surgery can be said to have justified itself in the treatment of bronchial carcinoma.

It is therefore imperative that as a profession we should be on the alert to diagnose these cases early, so that the small proportion of favourable cases should not be robbed of the chance of cure or relief that is open to them.

EXPLOSIVE EPIDEMIC OF SONNE DYSENTERY

BY

C. A. GREEN, M.D., Ph.D., D.P.H.

Surgeon Commander, R.N.V.R.; Royal Naval Medical School
AND

M. C. MACLEOD, M.D., D.P.H.

Recent investigations of outbreaks due to *B. dysenteriae* Sonne have stressed the importance of carriers and ambulant cases in the spread of disease (E.P.H.L.S., May, 1942; Hobbs and Allison, 1942). In rare instances milk has been shown to be a direct vehicle of infection, as reported by Scott (1938) and Faulds and Gavin (1942), while more frequently milk or milk dishes have been suspected, but without final proof being obtained (Graham, 1942; E.P.H.L.S., May, 1942). A search of the literature has not revealed any instance of an epidemic in which the possibility of water-borne infection was subsequently supported by laboratory evidence. For this reason the circumstances attending the onset of an outbreak in a Somerset town are recorded.

While diarrhoea of a mild and indeterminate nature has been observed in this district for some years it was not until Sept. 1941, that *B. dysenteriae* Flexner was isolated from a number of the affected individuals. This small outbreak quickly subsided and few secondary cases developed. Since that time the community has been relatively free from dysentery until the serious outbreak in July, 1942.

Onset of the Epidemic

The earliest noted case was that of a young boy whose initial symptoms of nausea and vomiting were diagnosed as acute appendicitis. Operation was followed by diarrhoea. This led to the unmasking of ten cases in children who were all day scholars or boarders at a small private school. Within a week many cases were seen, and it was evident that residents in all parts of the town were simultaneously affected. *B. dysenteriae* Sonne was isolated on desoxycholate-citrate agar (Hynes, 1942) from the stools of the first six cases examined. The epidemic involved both sexes, at all ages from 2 to 80 years.

The total number was uncertain, as the only cases for which medical aid was invoked were the children and older people. It was estimated that from July 14 to July 20, the first week of the epidemic, there were no fewer than 200 cases. Within the first month the total of cases was close on 400 out of a population of 10,000.

Clinical Notes

In the individual case the onset was heralded by sudden prostration, with headache, slight rigor, rise of temperature to 101° F., sickness and vomiting, colic, and diarrhoea. Stools were usually profuse and watery, offensive, with blood and mucus intermingled. Fever tended to subside within three to five days, but in some cases the acute phase lasted a week. Relapses were common, especially in children who clamoured successfully for more solid food soon after the acute phase was over. Post-dysenteric colitis was noted in several subjects. The administration of salines with a light fluid diet, continued for several days after the cessation of diarrhoea, was the general line of treatment. Astringent sedatives for the arrest of persistent diarrhoea and colic were required in many cases.

Distribution of Cases

Cases were distributed at random all over the town. Owing to the fact that a relatively small proportion sought medical advice it was impossible to state categorically whether any area was affected more than others. The larger proportion of notified cases resided in the upper part of the town, due probably to the fact that it was occupied by the wealthier section of the community, who were more likely to seek medical advice.

In addition to the main town, a small village derived its water supply from the same source, although the water was stored after chloramination in a reservoir used solely by the village. The volume of the water in the reservoir was such

hat the period of contact with the chloramine used for purification was over four days. Not one case of dysentery occurred in this village during the time of the epidemic in the town.

Milk and Water Supply

The first 30 cases notified, including those in the original chol epidemic, were supplied with milk from one particular dairy, but repeated examinations of the milk for *B. dysenteriae* Sonne were negative. Furthermore, the milk in question was obtained from a farm which sent the remainder of its supply to another retailer, who delivered in bulk and had few dysentery cases among his large clientele.

The water supply for the entire town was derived from two deep wells. Water was pumped in a 12-in. main from the distant well, two miles from the town, to the near well, which was situated one mile from the town. The entire output of the two wells was then pumped in a 14-in. main to two tanks, high and low level, from which the distributing mains passed to the town. From source to consumers the water was contained in a closed system save for the ventilating system of over-cowls in the collecting-tanks.

Treatment of the Water

First chlorination and later chloramination had been practised for several years on account of the increasing risk of pollution following upon the erection of dwelling-houses with cess-pits in the area draining to the site of the wells. Although conditions were not serious at the time when chlorination was initiated, the water company concerned had wisely considered it advisable to institute preventive measures, the control of which being outside their jurisdiction. In each well chloramination was effected by means of a pulsometer, the principle being that the chloramines were preformed in a small volume of water which was mixed with the main volume as it entered the rising main of the well. The ratio of chlorine to ammonia was two parts to one part, while the minimum duration of contact before delivery to the consumer was variable, depending on the locality of the consumer's residence. It was unlikely that the contact period was ever less than three hours, but equally certain that large volumes of water were used just after that period. This was due to the increased demand for water at peak periods of the day, resulting from a great increase in the wartime population. This increase was particularly felt in the lower portion of the town receiving its supply from the low-level tank. The above treatment was controlled by periodic estimations of the residual chlorine in a sample from the main pipe a few yards beyond the rising main of the wells. The amounts of chlorine and ammonia were adjusted to give 0.15 p.p.m. residual chlorine as tested by the orthotoluidine method. Repeated tests in houses supplied by high-level and low-level tanks showed little fall in this value, 0.12 p.p.m. being the lowest figure obtained.

Bacteriological Examination of Water

On July 24 a routine examination of the water from a tap at the laboratory which was supplied by the high-level tank gave the following result:

Growth at 22° C. . .	190 organisms per c.cm. . .	Residual chlorine 0.15 p.p.m.
37° C. . .	6	
Lactose fermenters . .	0	"
<i>B. coli</i> . . .	0	"
<i>Streptococci</i> . . .	0	"

At the same time six 100-c.cm. samples of water from the same source were each added, within 5 minutes of collection, to 10 c.cm. double-strength beef-digest broth. After 24 hours' incubation at 37° C. five bottles remained sterile and one bottle showed a turbid growth. Subcultures on MacConkey plates gave lactose-fermenting coliform colonies together with two ile colonies, both of which were examined fully. Both colonies gave identical results, the organism being a non-motile gram-negative bacillus with the following biochemical reactions (— indicates no acid or gas produced; +, acid but no gas produced).

Glucose	Lactose	Dulcitol	Saccharose	Mannite	Maltose
+	+	+	+	+	+
(late)					
Xylose	Arabinose	Inositol	Indole		
—	—	—	—		

Both strains were agglutinated to end-titre by Oxford Standards Laboratory sera, stated to be specific for *B. dysenteriae* Sonne, and rabbit antisera prepared against both strains agglutinated *B. dysenteriae* Sonne to titre.

On July 29 six 100-c.cm. samples of water were again tested as above, and all remained sterile.

An opportunity of testing the untreated water in the more remote well on Aug. 24 resulted as follows:

Growth at 22° C. . .	0 organisms per c.cm.
37° C. . .	5
Lactose fermenters . .	25
<i>B. coli</i> . . .	2
<i>Streptococci</i> . . .	0

The *B. coli* belonged to the atypical *coli-aerogenes* group.

On Aug. 27 the untreated water in the near well was also examined, with results as follows:

Growth at 22° C. . .	0 organisms per c.cm.
37° C. . .	15
Lactose fermenters . .	25
<i>B. coli</i> . . .	2
<i>Streptococci</i> . . .	0

The *B. coli* belonged to the atypical *coli-aerogenes* group. No dysentery organisms were isolated from either of the untreated waters, using a variety of media including desoxycholate agar.

The senior technician who took the sample of water from which the two colonies of *B. dysenteriae* Sonne were isolated was in good health, was not himself a carrier, and gave no history of past infection. Furthermore, he was employed daily in handling media used in the preparation of T.A.B.T. vaccine, and on no occasion has *B. dysenteriae* Sonne been found in media handled by him. The specimen of water was taken and the identification of the organism carried out in a laboratory to which *B. dysenteriae* Sonne had never been introduced, and all stages of identification were conducted by one of us (C. A. G.) personally.

Waterworks Employees

Eight employees of the water company had direct access to the water before distribution. All were examined, with negative results as regards present or recent intestinal illness. Their sera showed a complete absence of agglutinins for *B. dysenteriae* Sonne, although H agglutinins for *B. typhosus* to a titre of 1:250 persisted in four men inoculated at least 25 years previously.

Agglutinins for *B. dysenteriae* Sonne

Sera from seven cases were examined for agglutinins against *B. dysenteriae* Sonne. The accompanying table indicates that

Table showing the Agglutinin Titre of Sera from 7 Typical Cases. *B. dysenteriae* Sonne (Oxford Standards Laboratory Suspension)

Case	Age in Years	Duration of Acute Illness in Days	Days from Start of Illness to Time of taking Blood Specimen	Serum Dilution				
				1:10	1:25	1:50	1:125	1:250
1	35	3	13	+++	++	—	—	—
2	30	2	16	+++	+++	+++	++	—
3	40	5	14	+++	+++	+++	+++	+++
4	31	6	14	+++	+++	+++	+++	+++
5	10	4	10	+++	+++	+++	+++	+++
6	6	4	10	+++	+++	+++	+++	+++
7	34	4	1	+++	+++	+++	+++	+++

* Sera from eight healthy individuals in same locality were all negative at a dilution of 1:10.

agglutinins afforded a useful confirmation of the diagnosis in the few cases examined, only one failing to respond. Relatively high titres were recorded for the two children in the group. In one case the criterion of a rising titre was obtained. As controls, sera from eight healthy volunteers from the same locality and without history of recent diarrhoea were examined. No agglutination was detected in any serum even in a dilution of 1:10.

Action Taken to Prevent Further Infection

The isolation of *B. dysenteriae* Sonne from chloraminated water led to immediate experimental work, still incomplete, which suggested the strong possibility that the dosage of chloramine in use was too small for the shortest possible contact period. Accordingly the amount was raised so as to give a

residual chlorine reading of 0.4 p.p.m. At the same time the ratio of chlorine to ammonia was increased from two to four parts of chlorine to one of ammonia with the object of accelerating the process of sterilization. After this step had been taken a few cases of dysentery continued to occur, but seldom was it impossible to find a history of contact with a previous case.

Discussion

The character of the epidemic suggested some general source of infection such as a common food or water. The fortunate circumstances under which *B. dysenteriae* Sonne was isolated from a sample of water precluded the possibility of a sampling error having been made. The disturbing feature was the fact that the sample of water satisfied the usual standards for purity, and that 0.15 p.p.m. residual chlorine was still present. This appeared to be a direct contradiction until it was found experimentally that *B. dysenteriae* Sonne could survive after treatment with this strength of chloramine for periods longer than those applicable to many of the consumers. The position was rendered more dangerous by virtue of the fact that the chlorine-ammonia ratio of 2:1 was such as to delay considerably the sterilization process, as shown by Elliott (1933). Notwithstanding the satisfactory results of the single tests performed on the raw well-waters and that subsequent tests of the treated water were invariably negative, the fact remained that cess-pits were in existence in the drainage area and the water therefore remained suspect.

The apparent connexion observed at the onset of the epidemic between one particular milk supply and a group of cases was interesting in the light of the finding of *B. dysenteriae* Sonne in the water supply. The dairyman concerned was in the habit of rinsing his bottles with cold tap-water after they had been sterilized by steam, and probably introduced the infection to his supply in that manner.

Flies were considered as possible vectors which may have produced an explosive epidemic, particularly as the town sewage is discharged untreated into the sea at no great distance from the town. At the time of the present epidemic, however, there were remarkably few flies in evidence—a fact commented upon by many observers. When the epidemic had practically subsided the usual summer increase in the fly population developed without stimulating further infection. This fact appeared to minimize the importance of flies in this particular epidemic, for with the persistence of the carrier state (E.P.H.L.S., Nov., 1942; Hobbs and Allison, 1942) ample opportunity must have occurred for the transference of infection from faeces to town during the period of heavy fly infestation.

Summary

An outbreak of Sonne dysentery involving approximately 400 cases is described.

Milk was excluded as a general source of infection, although probably indirectly responsible for one small group of cases.

B. dysenteriae Sonne was isolated from one sample of tap-water which passed the usual bacteriological tests satisfactorily and which contained 0.15 p.p.m. residual chlorine.

The evidence for incriminating the water supply as the source of infection is discussed.

We wish to acknowledge with thanks the willing co-operation of the director and staff of the water company, the milk retailers, and the blood donors during the investigation.

According to a law introduced in April, 1942, everyone in Norway who has reached the age of 15 years must have his lungs examined by screen photography when the authorities demand it. Persons exempt from this obligation are those who have been x-rayed at school or who are notified cases of pulmonary tuberculosis and have been x-rayed within twelve months of the time they reach the age of 15. When the examination has been completed, information to this effect is stamped on the person's identity card (*Tidsskrift for Norges Lægeforebund*, July 1, 1942, No. 13).

INFECTIVE HEPATITIS TREATED WITH GLUCOSE, INSULIN, AND ASCORBIC ACID

BY

D. R. MACDONALD, M.B., Ch.B.

Sudan Medical Service; Senior Medical Inspector, Omdurman Civil Hospital

Infective hepatitis (syn., infective jaundice, epidemic catarrhal jaundice) is an endemic disease in Omdurman. During 1942 50 cases were admitted to Omdurman Civil Hospital, a native hospital of 215 beds. Of these cases 42 fell in the age group 10 to 33 years. The duration of the disease was 2 to 7 weeks (average 23 days). From time to time minor epidemics of the disease have occurred, and these have often included one or two severe cases resembling acute liver atrophy which have ended in death from profuse bowel haemorrhage. Various forms of treatment have been tried, including massive doses of glucose, intravenous drip infusions of glucose and alkali, intravenous sodium thiosulphate, and repeated medical drainage of the gall-bladder. None of these measures has appeared to have had the slightest effect upon the course of the disease. Recently El Kaimakam H. J. Bell (then vénérologist to the Sudan Defence Force) read a paper to the Sudan Branch of the British Medical Association on "Arsenical Toxaemia." In his paper Major Bell described some very striking results which he had obtained by the use of glucose, insulin, and ascorbic acid in the treatment of late toxic conditions resulting from the treatment of syphilis by neoarsphenamine. These cases included arsenical jaundice. Major Bell's paper suggested a possible new line of treatment for infective hepatitis, particularly as there is a good deal of evidence to suggest that arsenical jaundice may be due to the synergic action of neoarsphenamine and the causal agent of infective hepatitis, probably a virus. Accordingly five consecutive cases of infective hepatitis admitted to Omdurman Civil Hospital were treated on these lines, and a summary of the case records is given below.

Case I

A Sudanese male aged 26 was admitted on Feb. 16, 1943, with a complaint of jaundice for 4 days, accompanied by nausea, flatulent dyspepsia, and constipation. There was no history of syphilis or of treatment by arsenicals.

Condition on Admission.—Afebrile; moderately severe jaundice; tongue coated; liver dullness normal; spleen not palpable. Urine: bilirubin and bile salts present; no albumin. Stools clay-coloured. Blood: no malarial parasites. White cell count, 8,200 per c.mm.—polymorphs 53%, lymphocytes 44%, large mononuclears 1%, eosinophils 2%. Capillary resistance test normal.

Progress and Treatment.—Feb. 17: Condition unchanged. Treatment started: glucose by mouth, 5 oz. daily; insulin, 10 units twice daily; tab. ascorbic acid (25 mg.), three tablets thrice daily. Temperature rose to 99.2° in the evening. Feb. 18: Afebrile; trace of jaundice. Feb. 20: Afebrile; no jaundice; no symptoms.

Case II

Sudanese male aged 38, admitted Feb. 7, 1943. Severe lumbar pain for 5 days and jaundice for 3 days with flatulent dyspepsia, nausea, and constipation. He had no history of syphilis or of treatment by arsenicals.

Condition on Admission.—Afebrile; very deeply jaundiced; tongue coated; liver dullness slightly diminished; spleen not palpable. Bilirubin and bile salts present in urine, with a trace of albumin. Stools clay-coloured. No malarial parasites in blood. White cell count, 9,800 per c.mm.—polymorphs 51%, lymphocytes 45%, eosinophils 4%. Large mononuclears were absent. Capillary resistance test normal.

Progress and Treatment.—Afebrile throughout. Condition remained unchanged until treatment started. Feb. 16: Treatment with glucose by mouth, 5 oz. daily; insulin, 10 units twice daily; tab. ascorbic acid (25 mg.), three tablets thrice daily. Feb. 18: Jaundice greatly decreased. Feb. 20: A faint icteric tinge only could be detected on the conjunctivae. Feb. 22: Jaundice gone; no symptoms.

Case III

Sudanese female aged 22, admitted Feb. 14, 1943, complaining of jaundice, dyspepsia and continuous nausea for 7 days, and constipation. There was no history of syphilis or of treatment by arsenicals.

Condition on Admission.—Afebrile; moderately severe jaundice; tongue coated; liver dullness normal; spleen not palpable. Bilirubin and bile salts present in urine, and a trace of albumin. Stools clay-coloured. No malarial parasites in blood. White cell count, 8,500 per c.mm.—polymorphs 55%, lymphocytes 40%, large mononuclears 3%, eosinophils 2%. Capillary resistance test normal.

Progress and Treatment.—Temperature rose to 99.2° on evening of Feb. 15 and to 99.8° on evening of the 16th; otherwise afebrile. Feb. 16: condition unchanged. Treatment started: glucose, 5 oz. by mouth daily; insulin, 10 units twice daily; tab. ascorbic acid (25 mg.), three tablets thrice daily. Feb. 17: Trace of jaundice. Feb. 19: Jaundice nil; no symptoms.

Case IV

Sudanese male aged 9 years, admitted Feb. 15, 1943, having had jaundice for 7 days, with constipation. There was no history of treatment by arsenicals.

Condition on Admission.—Afebrile; moderately severe jaundice; no signs of congenital syphilis; tongue coated; liver dullness normal; spleen not palpable. Bilirubin and bile salts present in urine; no albumin. Stools clay-coloured. No malarial parasites present in blood. White cell count, 5,700 per c.mm.—polymorphs 39%, lymphocytes 56%, large mononuclears 3%, eosinophils 2%. Capillary resistance test normal.

Progress and Treatment.—Afebrile throughout. Feb. 16: Condition unchanged. Treatment started: glucose by mouth, 2 oz. daily; insulin, 5 units twice daily; tab. ascorbic acid (25 mg.), one tablet thrice daily. Feb. 18: Faint icteric tinge only to be seen on the conjunctivae. Feb. 19: No jaundice; no symptoms.

Case V

Sudanese female aged 70, admitted Feb. 17, 1943, complaining of jaundice for 30 days accompanied by flatulence and nausea. There was no history of syphilis or of treatment by arsenicals.

Condition on Admission.—Afebrile; emaciated; intense jaundice; liver dullness normal; gall-bladder and spleen not palpable; nothing abnormal discovered clinically elsewhere. Bilirubin and bile salts present in urine; no albumin. Stools clay-coloured. No malarial parasites in blood. White cell count, 4,800 per c.mm.—polymorphs 61%, lymphocytes 34%, large mononuclears 4%, eosinophils 1%. Capillary resistance test normal.

Progress and Treatment.—Afebrile throughout. Feb. 18: Treatment started: glucose, 5 oz. by mouth daily; insulin, 10 units twice daily; tab. ascorbic acid (25 mg.), three tablets thrice daily. Feb. 21: Condition unchanged.

Note.—In view of the patient's age, the intense degree of jaundice without haemorrhages and without diminution of liver dullness, and the emaciation, this may well be a case of carcinoma of the head of the pancreas.

Summary

The treatment is described of five cases of infective hepatitis, taken at random, by glucose, insulin, and ascorbic acid. In Cases I, III, and IV there was complete remission of all symptoms and signs in 3 to 4 days. In Case II, a severe one, there was marked improvement in 4 days. In Case I the disease lasted only 9 days (the lowest time recorded in Omdurman Civil Hospital); in Case III it lasted 14 days, in Case IV it lasted 12 days. All these times are well below the average of 23 days. In Case V, in which, however, for the reasons stated above, there was cause to doubt the accuracy of the diagnosis, there was no change.

Although it is appreciated that it would be rash to base conclusions on the results of a series of only five cases, nevertheless, in view of the importance of this disease and in view of the striking results obtained in three of the cases, it has been considered desirable to place these notes on record without delay.

I wish to acknowledge my indebtedness to the Director, Sudan Medical Service, for permission to publish these case records; to Major H. J. Bell for his valuable paper on arsenical toxæmia; and to Dr. Mahmoud Hussein for his assistance in compiling the records.

LIVER DEFICIENCY ANAEMIA IN A CASE OF ACUTE INFECTIVE HEPATITIS

BY
J. NORMAN HILL, M.B., Ch.B., D.P.H.
AND
WALTER HAUSMANN, M.D. Vienna

The following is an account of a case of liver deficiency anaemia which occurred acutely during the course of an infective jaundice. There was slight anisocytosis and practically no poikilocytosis, and the anaemia responded with a clear-cut reticulocytosis to injections of liver, the only haematinic employed. There was no associated achlorhydria or even hypochlorhydria, nor were there any nervous symptoms. The condition would appear to have been due solely to the effects of liver damage, as there had been no evidence of gastric disturbance since admission and the anaemia developed while the patient was in hospital.

Case History

The patient is a gamekeeper on a moorland estate in Yorkshire, and was known to one of us (J. N. H.) before he developed jaundice. He was a robust man of 52 years who had never had any previous illnesses, who did not smoke, and who was practically teetotal. His son, aged 18, had had jaundice for two weeks—four weeks before the patient contracted it—and the patient himself had had it for five weeks before he was sent to the County Hospital, Otley. He had continued to work almost up to the day of admission, Oct. 2, 1942. The incubation period of four weeks is mentioned by Dr. W. N. Pickles (1942) in his Milroy lectures. He also remarks that the disease frequently visits Wensleydale, and we have noticed quite a crop of cases in Wharfedale during the past two years.

By the time the patient was admitted he had lost a considerable amount of weight, largely owing to anorexia, which had caused him to take practically nothing to eat during the two previous weeks. He was profoundly jaundiced, and suffered from intense itching of the skin due to this. His stools were clay-coloured, and his urine was loaded with bile pigments and contained a small quantity of urobilinogen. His liver was grossly enlarged, extending down to the umbilicus, and its surface smooth; his spleen protruded four very hard. Examination revealed no other noteworthy physical findings, and the nervous system was normal.

A blood count on admission gave the following results: R.B.C., 4,800,000; Hb, 98% Sahli (throughout); C.I., 1; W.B.C., 3,300—polymorphs 58%, lymphocytes 33%, monocytes 5%, eosinophils 2%, ribbon forms 2%. The polymorphs showed toxic granulations. The van den Bergh test gave a direct positive result. The Wassermann test was negative.

The patient was put on a carbohydrate diet with copious glucose drinks, and vitamins in the form of Abbott's pentacaps 2 t.d.s. for the first three weeks. By that time his appetite had completely returned, and he then took a normal diet with added carbohydrate drinks. The leucopenia was checked again on Oct. 29 and Nov. 4 and 12, and showed totals and differentials very similar to the original count except that the percentage of ribbon forms rose to 12.

Towards the latter end of this period we had noted with concern that, although the patient was improving generally and eating well, a greenish-grey pallor was showing through the jaundice, so on Nov. 20 we did another complete blood count, and were astonished to find: R.B.C., 2,300,000; Hb, 63%; and C.I., 1.37. The film revealed slight anisocytosis, with macrocytosis, hyperchromia, polychromasia, and a few nucleated red cells. The white cell count—3,200—and the differential count showed no significant change from those noted above. The reticulocytes appeared to be approximately normal, although an actual count was not made on this specimen.

A sternal puncture was done immediately, and after examination the smears were sent to Edinburgh.

Dr. L. J. Davis reported on them as follows: "The film is a 'thin' one in which marrow cells are scanty. Marrow cells of all types are present. Erythropoiesis is normoblastic; although a number of basophil erythroblasts are present, megaloblasts typical of pernicious anaemia in the relapse stage are not seen. No gross abnormality is noted in the white cell series; there is perhaps an increase, however, in the proportion of promyelocytes."

Unfortunately, owing to a technical difficulty, we could not at this time carry out a fractional test meal examination, but on Nov. 25 we were able to do so. It showed a mild hyperchlorhydria, delayed emptying, and bile in the first three and last three specimens. Mucus was present only in the fasting juice.

Liver injections were started on Nov. 20—initial dose 8 c.cm. neohepatex Evans, 2 c.cm. daily for seven days, then 2 c.cm. every other day for two weeks. This was not sufficient, and so 2 c.cm. daily was given from Dec. 10 until Jan. 6, 1943, when it was stopped to see if a relapse would occur. We should like to emphasize that liver was the only haematinic given.

A second sternal puncture done on Nov. 26 showed an essentially similar picture. There were then 6.7% reticulocytes, and the haemoglobin was 73%. Further reticulocyte counts showed: Nov. 28, 3.5%; Nov. 30, 3.6%; and Dec. 2, 2.8%. By Dec. 4 the haemoglobin was 85%, R.B.C. 3,700,000, and C.I. 1.15; and on Jan. 5, 1943, at the end of liver therapy, Hb 92%, R.B.C. 3,900,000, and C.I. 1.25, and the white cells had risen to 7,400. A further count, on Jan. 19, gave Hb 95%, R.B.C. 4,400,000, C.I. 1.1, and W.B.C. 10,700. Reticulocyte counts done during this period were normal.

Meanwhile the patient's clinical condition was steadily improving. The jaundice was slowly disappearing, his appetite was excellent, his liver and spleen were both receding, and he was beginning to gain weight. His condition on Jan. 26 was very good; he had gained 16½ lb. in the last four weeks, and weighed 11 st. 13 lb. He could undertake without fatigue a stiff uphill walk of an hour's duration to his home on the moor-tops. His liver was still palpable and his spleen only just palpable. The faintest trace of jaundice could be seen in his skin and sclerotics. The van den Bergh reaction continued to be positive direct until Feb. 26, but on April 14 and May 14 the results were negative. A blood count on June 9 showed Hb 95%, R.B.C. 4,750,000, and C.I. 1. No trace of jaundice was then to be seen. The liver and spleen were just palpable. The patient's general condition was excellent.

Comment

We feel that the response to liver therapy certainly suggests that the anaemia was due to lack of liver principle; on the other hand, it is conceivable that the improvement in the blood picture might have occurred spontaneously after the patient's recovery from his infective condition. The reticulocyte response would, however, support our own view.

Regarding spontaneous recovery, it is interesting to note that in the only case of macrocytic anaemia associated with acute catarrhal jaundice about which we have been able to read so far (Wintrobe and Shumacker, 1933), spontaneous recovery did occur. In their case, however, the origin of the jaundice was not so clear, there was no splenomegaly, and there was a histamine-fast achlorhydria to begin with. The anaemia cleared in 24 days, whereas in the present case, even assisted by liver extract, recovery to the level of 4,400,000 took 52 days. These authors encountered macrocytosis in 11 out of 43 cases of hepatic disorder, and of these eleven the case quoted above was the only one suffering from acute catarrhal jaundice. They performed necropsies upon 8 cases, and note that the pathologist described the extent of the liver destruction as extreme in the very same four cases in which hydrochloric acid was found in the gastric contents, but that no such comment was made in the other four cases, in which achlorhydria was present.

We are aware that this case is unsupported by mean corpuscular volume figures and that other investigations might with advantage have been carried out, but we feel that the case has sufficient importance to warrant publication if only so that others may be aware of the possibility of a grave anaemia complicating acute infective hepatitis and be prepared, for it to be of liver-deficiency type.

We have during the conduct of the case enjoyed the most helpful and encouraging correspondence with Prof. L. S. P. Davidson and Dr. L. J. Davis of Edinburgh. I have to thank them, too, for permission to quote the above report from one of their letters.

AETIOLOGY OF THE FIBROSITIC NODULE: A CLINICAL CONTRIBUTION

BY

W. S. C. COPEMAN, M.D., F.R.C.P.

Lieut.-Col., R.A.M.C.; Officer in Charge of a Medical Division

The term "nodule" is employed in the title of this paper (which expresses my own views alone) as it is one that has been familiarized by custom. It has seemed, however, that the existence of a nodule definite enough to be palpated in the muscles of a sufferer with fibrositis must in most cases be a sign of chronicity of the complaint, and that the "myalgic spot" is probably an earlier stage of what later becomes a nodule if left untreated. The discrepancy in the frequency with which nodules are found in this disease in England and in America can be explained by this hypothesis.

The myalgic spot is an area of hyperaesthesia in the substance of a muscle or its tendinous sheath which gives rise to pain either in the same locality or referred to a distance, when stimulated. We owe mostly to Kellgren the description of this referred pain and its distribution. These spots are generally multiple, and occur in the powerful muscles of the back and of the gluteal region, often towards the edge of the muscle where it blends with the more fibrous portion. They may also occur, but less often, in the peripheral muscles, and in the anterior muscles of the trunk.

The aetiology and pathology of the myalgic spot or nodule are unknown, although trauma is believed by most observers to play a part in its development. It is thought that the observations recorded below throw some light on the aetiology in a proportion of cases.

Observations of Acute Myalgia

An epidemic of influenza was recently studied in which severe pain in the lower back was an early and prominent symptom in nearly every case. Some patients also complained later of pains in the thighs, calves, and arms. The cases comprising this epidemic were all of the "febrile" type described by Horder and Gow (Price's *Medicine*, 1941) as being of abrupt onset, with pyrexia and associated malaise and headache in addition to the pains described above. The pyrexia was high for three to five days, and was accompanied by a moderate degree of catarrh, chiefly affecting the eyes. Defervescence was by rapid lysis, and a leucopenia was present in most cases. None of the 40 patients examined had any previous history of rheumatism.

It was noted in the course of this epidemic that, although the acute lumbar pain was diffuse, severe, and resulted in spasm in some cases, by careful examination it could be found that it radiated from localized hypersensitive areas in the adjacent muscles, and that the position of these areas approximated to those usual in cases of ordinary lumbago. The same observation was made in cases in which the pain was in the limbs. In one instance severe "crampy" pain in the upper portion of the rectus abdominis muscle was also present—the clinical picture being comparable to that of epidemic myalgia (Bornholm disease). This pain was entirely relieved by an injection of procaine at the focal point.

The subjective pain disappeared after two or three days, but these myalgic spots were found by palpation to be still present, although the patient was not aware of them. When found and pressed on, he felt a sudden sharp pain which made him wince momentarily and which was—in about half the cases examined—referred in addition to the whole area previously affected. The number of such spots which could be discovered in any patient tended progressively to decrease as time went on.

The same group of patients were again examined two months after their influenza, when it was found that only in rather less than half of them could these spots still be found. In these cases, as before, the patient was himself unaware of their presence until examination. Three cases deserve special mention.

Reports of Three Cases

Case 1.—A civilian aged 40 had a sudden onset of headache, with pain behind the eyes, sweating, and malaise. Pain in the back had occurred several hours previously, and this got progressively worse. For this reason the patient preferred walking about to lying in bed, although his temperature was 102.6°. On examination he looked ill and was sweating profusely. The eyes were congested and the tongue furred. Pain in the back was evidently severe, and the muscles appeared to be in spasm. Urine and stools were normal, and no malarial parasites were present in the blood. The white cell count was 5,000. Next day he was much better. There was still pain behind the eyes and in the back. The temperature was normal. Myalgic spots were found in the lumbar region. The patient made an uninterrupted recovery until three weeks later, when he developed mumps. The pain then returned to the lumbar region as at first, although not so severely, for two days, during which the temperature was raised above 100° F.

Case 2.—A civilian aged 27 complained of sudden onset of severe pains in head, back, and legs, with a feeling of pyrexia, the previous afternoon. Temperature was 101.6° and pulse 90 when seen, and he was sweating profusely. No shivering; bowels rather loose on previous day but now constipated. Patient looked ill; tongue lightly furred. On examination nothing abnormal was found in the abdomen, and there were no malarial parasites in the blood. W.B.C. 3,400. The pains had prevented much sleep previously, but sedatives gave some relief. One week later pain and other symptoms had entirely gone, and the patient had resumed work. Pain could, however, be provoked momentarily by pressure on the myalgic spots which still persisted in the lumbar region and along the border of the ilium on both sides. Two weeks later the condition was unchanged, excepting that fewer of these spots could be found. Those present were carefully marked. Five c.cm. of blood, taken in the first 12 hours from a patient who had just developed sandfly fever, was then injected intramuscularly—by permission—and on the next day a pyrexial attack with a maximum temperature of 101° developed, and lasted 36 hours. The patient complained of lumbago from the onset of this pyrexia, and on examination it was found that this pain was originating from the spots which had been marked. It was easily abolished by injecting 1% novocain into them. One month later this patient was still found to have three myalgic spots in the lumbar region of which he was completely unaware.

Case 3.—A gunner aged 22 experienced a sudden onset of severe occipital headache with pains in back and legs. Temperature 101°. On examination he looked, and felt, very ill. There was marked congestion of the conjunctivae, and the bowels had been rather loose for two days. Tongue moist, with light-brown fur; abdomen normal; stools and urine normal; W.B.C. 4,200. Pains disappeared on third day; temperature normal and all symptoms gone on fifth day. Two weeks later the patient stated, when seen, that he was perfectly fit, but well-defined myalgic spots were found in the lumbar region. On pressure these referred a pain down the legs entirely comparable to that which had occurred during onset of fever. This patient was seen again a month later for another reason, and volunteered the information that similar pains had returned, although in a less degree, for a short period a few days previously while a cold in the head was developing.

From these observations it seems that infection with the organisms of influenza will produce acute muscular pain which can be shown to be referred from myalgic spots that develop in the region of the affected muscles. The spots appear to resemble those found in cases of ordinary lumbago. A large proportion of the spots which were seen to develop in the present series of cases disappeared a few days after the termination of the influenza, but some of them survived.

It does not seem that these myalgic spots are a specific reaction to the virus of influenza as such, however, in view of the fact that the pain returned temporarily in the same areas during an attack of mumps which one of the patients (Case 1) developed spontaneously during convalescence. This view was confirmed experimentally by inducing an attack of sandfly fever artificially in a patient convalescent from influenza (Case 2), with the same result. It also seems possible (Case 3) that periodical attacks of the common cold or other mild virus infection may prove to be a factor in keeping myalgic spots which have arisen in this way active, although confirmatory evidence is lacking. If this were found to be so it suggests an analogy with the "maintenance dose" in other fields.

Observations on Myalgia following Exanthemata

It is well known that acute muscular pains may arise in the course of, or after, many of the acute infectious diseases other than influenza—chiefly, it would seem, those of virus

origin. A considerable number of patients complaining of it that had arisen in this way have been examined during past year. These pains have also in the majority of cases been found to have their origin in well-defined hypersensitive myalgic spots from which the patient's myalgia or "neuritis" (muscular tenderness) was referred. The diseases which commonly give rise to this syndrome appear to be sandfly glandular, undulant, and scarlet fevers, measles, and rubella. Myalgic spots arising during the course of one of these diseases have been found to be still present two months later, this being the longest period during which a "follow-up" proved possible in this series.

The description already given of the myalgic spots arising during the epidemic of influenza applies equally to those arising in this series, and justifies the belief that they appear during the course of almost any acute infectious fever and that a certain proportion will persist unknown to patient until such time as they may subsequently be reactivated.

It seems probable that factors such as chill, damp, trauma and mild focal infection, which have sometimes been held to be causative, are in fact of secondary importance, and provoke an attack of fibrositis or myalgia only in the presence of latent myalgic spots formed previously in this way. A method by which they actually provoke an attack may possibly be by inducing a local oedema in the sensitive area, when the victim becomes aware of the myalgic spot and of pain referred from it. If this is so it accounts for the nodal feeling which is not infrequently remarked at these points, the fact that this can sometimes be rubbed away by a skilled masseur.

Summary

The role of "myalgic spots" or "rheumatic nodules" in fibrositis is discussed.

In a recent epidemic of influenza in which lumbar and other was a prominent feature it was observed that this pain was referred from small hypersensitive areas in the muscles. These were indistinguishable from "rheumatic" myalgic spots. On re-examination of the patients after one and two months these were still found to be present, although in diminishing number. The patient was, however, invariably unaware of this fact; pressure from the examining finger disclosed them. None of the patients had any previous rheumatic history.

Myalgic spots which had arisen during influenza were reactivated in one patient by an attack of mumps which arose spontaneously during convalescence. In another case this occurred as the result of the artificial induction of an attack of sandfly fever by the injection of infected blood. It appears, then, that myalgic spots arise *de novo* in the course of acute influenza, and that these persist in a proportion of cases. They can, however, be reactivated by infections of other types. In one case there was evidence suggesting that the common cold provided the means for maintaining activity of the myalgic spots.

Rheumatic pains are a characteristic sequel of many of the exanthemata, mostly those of virus origin. Observation has shown that these pains, which tend to arise in a less acute manner also generally of the focal type.

The final suggestion is therefore that the myalgic spots which is now widely agreed form the basis of many of the rheumatic syndromes of later life are sometimes a legacy from acute infection in earlier years. It is important to remember that the victim is often unaware of their presence until they become activated by factors such as chill, trauma, or focal sepsis. These factors should consequently be regarded as secondary and no longer causative in such cases.

My thanks are due to the D.M.S., Paiforce, and to Major R. E. Barnsley, M.C., D.D.M.S., Southern Command, for permission to publish this paper, and to Dr. H. Jamieson, chief medical officer of the Anglo-Iranian Oil Company, for his help.

Thirteen out of 20 patients with eclampsia were found by Rosenbaum and G. L. Maltby (*Arch. Neurol. Psychiat.*, Chicago, 1943, 49, 204) to have electro-encephalograms indicative of cerebral dysrhythmia. They compare this with the finding of similar changes in only 2 out of 20 patients with pre-eclampsia. Twelve of the eclamptic patients had a family and personal history of convulsions. The authors therefore suggest that in eclampsia there may be a primary cerebral dysrhythmia, and that the associated toxæmia may be the "trigger mechanism" which sets off convulsions.

VITAMINS AND PHYSIOLOGICAL FUNCTION

BY

G. NEIL JENKINS, Ph.D.

St. Bartholomew's Hospital Medical College

AND

JOHN YUDKIN, Ph.D., M.D., F.I.C.

Dunn Nutritional Laboratory, University of Cambridge and
Medical Research Council

A report has recently appeared from Manchester University of some observations in which a short period of supplementary feeding with vitamins produced significant changes in physiological function (Harper, Mackay, Raper, and Camm, 1943). The supplement, consisting of 6,000 I.U. vitamin A, 1,000 I.U. vitamin D, and 50 mg. vitamin C daily, was given to 35 cadets aged 18 to 19 for a period of 10 weeks, while 34 cadets received control pellets and capsules. At the end of 10 weeks the groups were changed over, so that the control group now received the vitamins for 11 weeks. The cadets had recently joined the Forces; during their training they were receiving, at the University refectory, a diet similar to that of the undergraduates. It was found that the group receiving the vitamins were superior in several respects to the control group: the vital capacity, breath-holding time, endurance (R.A.F. 40-mm. mercury test), and, surprisingly, the resting pulse rate, were all considerably increased in the vitamin-fed group. In addition there was a significant difference in the number of days during which the cadets complained of minor respiratory or gastro-intestinal disorders, those receiving the pellets having on the average 9.7 days of complaints per man, compared with 14.9 days per man in the control group. On the other hand, no difference was found in height, weight, chest girth, or pelvic measurement, nor in the standing pulse rate, the pulse rate during the R.A.F. endurance test, the post-exercise pulse rate, or the post-exercise vital capacity.

As it happened that elementary-school children were available in Cambridge who, in the course of other investigations, had been receiving vitamin pellets for a year, it seemed that the opportunity might usefully be taken to examine the general applicability of the findings of the Manchester investigators. To this end we have repeated the tests on the four functions which these workers found to be affected.

TABLE II.—Effect of Vitamin Supplements on Physiological Function

* Surface area not available for all subjects.

Experimental

Altogether 178 children have been examined; these comprised 80 12-year-old girls, 76 12-year-old boys, and 22 11-year-old boys. About half in each group—alternate children from the school register—had received vitamin pellets daily at school and the remainder control pellets. The vitamin pellets contained 5,000 I.U. vitamin A, 1 mg. vitamin B₁, 25 mg. vitamin C, and 500 I.U. vitamin D. The children were living and eating at their homes, except for some who had dinner at school. Allowing for week-ends and holidays, the average supplement over the year was roughly half the reputed daily requirements of these nutrients; apart from the vitamin B₁, which Harper *et al.* did not administer, the children were thus obtaining less of the supplemented vitamins than the subjects at Manchester.

The heart rate was measured over a half-minute period after the children had been sitting quietly and comfortably for 15 minutes, and again after a further 5 minutes. Preliminary tests had shown that this procedure gave much more consistent results than measurements taken with the children lying down.

The vital capacity was measured after the heart rate had been taken. It was found that the first one or two attempts were usually lower than subsequent attempts. Readings were therefore made until fairly consistent results were obtained, and the highest of these was taken as the true vital capacity; five or six attempts were usually sufficient. Owing to the variation in heights and weights of the children the vital capacity has been divided by the surface area in order to obtain a truer comparison.

Breath-holding was the time in seconds during which the subject could hold his breath after full inspiration, and the endurance test the time in seconds during which the subject could maintain, after full inspiration, a column of mercury at a height of 40 mm.

Half of the 12-year-old boys were examined three days after the completion of a vitamin C saturation test, during which they each received 70 mg. vitamin C daily per stone body weight (i.e., some 350 mg. daily on the average) for 5 successive days. A comparison was made of these 38 boys with the 38 who were not given the saturation test (Table I). (It might be

TABLE I.—Effect of Saturation with Vitamin C on Physiological Function

	Boys Receiving Vitamin Pellets		Boys Receiving Control Pellets	
	Saturated	Not Saturated	Saturated	Not Saturated
Number examined	19	19	15	23
Average resting pulse rate (beats per min.)	82.2	83.8	77	82
Average vital capacity (ml.)	2,310	2,142	2,297	2,145
Average vital capacity/sq. metre body surface	1,862	1,710	1,840	1,770
Average breath-holding time (secs.)	39.0	41.7	36.4	35.4
Average endurance test (secs.)	27.2	25.8	26.4	23.1

mentioned that all the boys subjected to the saturation test became saturated within the five days of the test, the majority within the first two days.) It will be seen that the differences between the "saturated" and "unsaturated" boys were in each case very small, and statistical treatment is hardly necessary to demonstrate that these differences are insignificant. We have nevertheless subjected some of the bigger differences to statistical analysis—for example, the apparent higher vital capacity in the "saturated" boys—and in each case the difference is not significant. This was also true when the "vitamin" group and the control group were combined.

We can therefore consider the "saturated" and "unsaturated" boys together, and compare those who had received the vitamin supplements with those who had not. Table II shows this comparison, together with the girls and the 11-year-old boys; none of the girls or the 11-year-old boys had been subjected to the vitamin C saturation test before the examination for physiological function.

It is evident from simple inspection that no significant difference exists between the subjects receiving the vitamin supplements and the controls. Such small differences as occur are often in opposite directions; thus the boys on the vitamin pellets have an average vital capacity, expressed as a function of their surface area, of 48 ml. less than that of the control group of boys; in the girls the value of the "vitamin" group is 38 ml. more than the control group. Also, considering all the children, whereas the average breath-holding time is higher in the vitamin group, the average vital capacity and the endurance time are slightly lower. Again statistical analysis confirms that none of the differences are significant.

Discussion

The Manchester workers have themselves pointed out some possible criticisms to which their results might be open. In particular, they refer to the small number of their subjects. Additional queries arise even although their results are statistically outside the limits normally accepted for chance variations (see Abrahams, 1943; also *British Medical Journal*, 1943).

If, however, we accept the validity of the findings of these workers, the fact that vitamin supplements did not induce such changes in physiological function in our subjects might possibly be due to their not having been deficient in these nutrients before the administration began. This is supported by the fact that there was also no improvement in other respects after the year's dosing (see Yudkin, 1943). Gain in height and weight, strength of grip, haemoglobin, intelligence, educational attainment, and dark-adaptation were no different in those children receiving the supplement from what they were in those receiving the control pellets. Moreover, although there was a reduction in the incidence and duration of colds in the vitamin group, this was seen only in the younger children and was not shown by the older children examined for physiological function.

It should be emphasized that the absence of effect in our subjects may be due to differences in age or in degree of deficiency; they are not therefore to be interpreted as contradicting the findings of Harper *et al.* Nevertheless it is clear that improvement of physical efficiency by vitamin supplements cannot be regarded as being generally applicable to all groups.

Summary

A group of 178 children aged 11 and 12 were examined after about half of them had received vitamin supplements daily at school for one year. The supplements provided each school day 5,000 I.U. vitamin A, 1 mg. vitamin B₁, 25 mg. vitamin C, and 500 I.U. vitamin D, the average addition over the year being about one-half of the reputed daily requirements of these substances.

No difference was observed between the control group and the supplemented groups in resting pulse rate, vital capacity, breath-holding, or 40-mm. endurance test.

THE CRY OF THE CHILD IN UTERO

BY

IAN M. JACKSON, F.R.C.S., M.R.C.O.G.
 Obstetric Registrar, London Hospital

"Vagitus uterinus" is the term applied to the crying of the child while its head is still in the uterus. Mohammed and Bartholomew are both supposed to have made themselves heard *in utero*. It may be of importance in medico-legal cases, as it is possible in this way for a child to be stillborn and have its lungs partly aerated. In some cases this cry of a child may also be a warning of foetal asphyxia, requiring rapid delivery.

Record of a Recent Case

Mrs. T., a primigravida aged 29, was sent up to the London Hospital at 40 weeks with a breech presentation. External version under anaesthesia failed and she came into labour spontaneously two days afterwards. The membranes ruptured after 27 hours with the cervix fully dilated, and 1½ hours later it was decided to assist delivery as the anterior buttock had been peeping without advance for half an hour and the mother was becoming distressed. The foetal heart rate was 160 a minute. The resident accoucheur performed a postero-lateral episiotomy under gas, oxygen, and ether, with the patient in the lithotomy position, but was unable to bring down a leg as there was little liquor. The registrar therefore took over, and just as he was passing his hand gently up the vagina the foetus was felt to give a convulsive movement and everyone in the labour theatre heard a "foetal cry." This was repeated twice more, and was accompanied by movement of the foetus. The cry was

loud, and was heard by three doctors, two hospital sisters, and nurses; and all this when the anterior buttock was just peeping the vulva. Rapid delivery was performed, bringing down the arms, and forceps was applied to the after-coming. Although this was done quickly the foetus was making inspiratory efforts during delivery. The female infant of 6 lb. was very cyanosed, but breathed at once and recovered rapidly.

Discussion

For this condition to occur it is necessary for air to be present in the uterus. This may be due to the suction of air along the examining hand during the relaxation of the uterus, as probably occurred in this case. If the patient had been delivered on the left side there would have been a tendency for gravity to pull the foetus and uterus out of the pelvis and so suck air into the vagina or even the uterus. Miss Field at the meeting of the Obstetric Section of the Royal Society of Medicine on March 19, 1943, described a case in which air rushed up the catheter during high rupture of the membranes and was followed by foetal crying, and 54 hours later by the delivery of a living child. Mr. Fraser's case at the same meeting was harder to understand. A 4-gravida 30 weeks pregnant, ruptured her membranes five days before delivery. Twenty-four hours before delivery the foetus was heard to cry *in utero* for 40 minutes with the os only one-fifth dilated. Tympanites and succussion splash were present. The premature foetus died with a cerebral haemorrhage three hours after delivery. Air was perhaps sucked into the uterus during a uterine relaxation, or by the piston-like action of the foetal head. Although afebrile there may have been a low-grade infection with gas-forming organisms.

Once there is air in the uterus the foetus must inspire in order to produce a cry. There are at least two types of intra-uterine cry. The first is a soft whimpering cry—best heard with a stethoscope to the abdomen—which may continue for a considerable time and is not associated with asphyxia of the infant. This was the type of cry in the latter two cases. The second type was found in our case, in which the cry was loud and gasping, and was accompanied by a convulsive movement of the foetus and associated with foetal asphyxia.

The work of Barcroft and Barron on the respiratory centre of lambs *in utero* throws light on this problem. The movement responsible for respiration can be traced back to the first efforts that the foetus makes, and it seems that a third of the way through pregnancy the essential neuro-muscular mechanism has been laid down and as it were tried out. At first the respiratory movements occur as a reflex to a stimulus. They become more sensitive and the response more differentiate but, later, with the development of the controlling high nervous centres the foetus again becomes inert. With the onset of labour there is a degree of anoxaemia which depresses the inhibiting higher centres, so that the foetus shows more movement. There is also an increase of CO₂ pressure, and an avalanche of sensory impulses which all have a large stimulating effect on respiration.

In the first group there is a gentle whimpering cry which is unassociated with asphyxia and occurs before or early in labour. This noise is due to air passing in and out of the chest, whereas normally there is a tidal flow of liquor. In these cases the foetus can be stimulated by prodding, where the cry may be louder. In the second group the type of respiration is gasping, is associated with foetal asphyxia, and occurs when labour is well advanced. It has been shown by Barcroft that transection of the brain-stem above the level of the hypoglossal nucleus in the sheep foetus causes this form of respiration, and it is suggested that this gasping type of cry in the human foetus is due to anoxaemia of the higher nervous centres releasing the lower medulla.

Yet another possibility is that once there is air in the body of the uterus it may be suddenly forced past a fold of membrane or vagina by a contraction of the uterus. A noise simulating a foetal cry might thus be produced. Sipple's case was quoted in the *British Medical Journal* of Sept. 14, 1911, while carrying out an internal version he had to hold the hand still during a contraction. At that moment there were two high-pitched noises just like an infant's cry, but he noticed that they were accompanied by a sensation of air running in his forearm.

It is probable that this condition is more common than supposed. Prof. F. J. Browne has found that the lungs of stillborn foetuses often float in water, which shows that some aeration has taken place. This post-mortem test of stillbirth is thus of little significance. DeLee said that he has heard babies sneeze and cough in utero, and even hiccup.

We have seen that at an early date in development the movements of respiration have been tried out. For a cry to be heard, however, there must be air in the uterus, with a variable degree of foetal anaemia, rise in CO₂ pressure, and peripheral stimulation. The cry will be quiet and whimpering if the asphyxia and peripheral stimulation are slight, but loud and gasping if these are severe. It is in the last group that the foetus is distressed and requires immediate delivery. In our case there is little doubt that air was drawn into the uterus along the examining hand between pains, and the long second stage and prolonged manipulation caused partial asphyxia and stimulation of the foetus. Rapid delivery possibly saved the child's life.

I must thank Mr. Eardley Holland and Mr. Alan Brews for permission to publish this case and for their help.

Medical Memoranda

Paralysis of the Serratus Anterior following Glandular Fever

So far only one case of this condition appears to be recorded in the literature, and that was by J. S. Richardson (*Lancet*, 1942, 1, 618); but in his case the paralysis developed during the third week of illness and cleared up in four months, whereas in the one which came under my observation—a persistent serratus magnus palsy following glandular fever—the paralysis developed five days later, and is still present a year after the onset.

CASE HISTORY

A soldier aged 25 developed a sore throat on April 27, 1942. A throat swab showed Vincent's organisms; culture negative for K.L.B. On May 8 there was a rise in temperature, with an erythematous rash over the chest and marked glandular enlargement in the neck on both sides. The spleen also was probably enlarged, but no enlargement of glands was noticed elsewhere. The rash disappeared after a few hours, but the temperature was still raised. It was thought to be a case of rubella, but as the patient had had a definite attack of rubella two years previously this was improbable. The glands continued enlarged and tender, and remained so for six or seven weeks.

On May 9 a white cell count gave 11,200 per c.mm.—neutrophils 29%, lymphocytes 66%, monocytes 4%, eosinophils 1%. There was severe pain in the right shoulder, with inability to sleep. On the 11th there developed severe paralysis of the right serratus anterior muscle with no sensory changes and no meningeal symptoms. Pain disappeared at onset of paralysis. The Paul-Bunnell reaction was positive in a serum dilution of 1 in 900. On the 12th the test was repeated, and was still positive at 1 in 900. Throat and nasal swabs were taken and cultured for K.L.B., but the result was negative; also, no Vincent's organisms were found.

On May 16 the white cells numbered 5,700 per c.mm.—neutrophils 39%, lymphocytes 51%, monocytes 9%, eosinophils 1%. The faradic response in the right serratus anterior was very weak. Radiographs of the cervical spine were negative. On June 22 lumbar puncture produced a clear fluid under normal pressure. No leucocytes were seen in 1 c.mm. Total protein, 45 mg. per 100 c.cm.; sterile. Since then the patient has had splinting and physiotherapeutic treatment.

On May 12, 1943, the vertebral border of the scapula, and especially the lower angle, still stood out prominently behind, giving a characteristic winged appearance to the back. The arm could be pushed forward, but weakly. I could not elicit any response to faradism or galvanism in the right serratus anterior muscle. Although the functional recovery is about 50%, it is obvious that this is due to the function of the serratus anterior being taken by other muscles, as that muscle is still paralysed.

Reviews

LOCAL GOVERNMENT

The Municipal Year Book and Encyclopaedia of Local Government Administration, 1943. (Pp. 1,343. 42s.) London: Municipal Journal Limited.

Many new matters have appeared on the agenda of local government since the *Municipal Year Book* was first published in 1897, so many that one wonders what Victorian aldermen and councillors found to talk about. The most recent matter and the most prepotent is civil defence with its various ramifications—provision and maintenance of shelters, arrangements for evacuation, communal feeding, care of the bombed-out, fire, first-aid, and decontamination services. It was argued at first, before experience disproved it, that to add civil defence to the other functions of local government would be, not indeed the last straw, but the last big bale of hay on this patient camel's back. But that was to reckon without the adaptability and resourcefulness of those who administer local affairs, especially the permanent local government service. Never before has local government touched life at so many points, and it has its reward in a quickened public appreciation which has displaced the old apathy. It is beginning to be realized by the average citizen that his happiness, safety, and environmental health depend upon the town hall more than upon the Palace of Westminster. This most important side of community life has a guidebook worthy of it. There is not a fact or figure, name or emblem connected with local government, from the city corporation down to the seven-hundredth rural district council, which is not to be found in these 1,300 closely packed and well-sectioned pages. The yearbook is primarily a directory, but it is also an annual review of the chief events in local government, and among other things it gives a good summary of the different reports, statistics, and tendencies in the field of public health. Incidentally it shows how various is the structure of local government. In England and Wales there are 62 county councils, 83 county borough councils, more than 300 councils of other municipal authorities, and nearly 600 urban district councils. A growing feature and sign of things to come is the number of joint boards and committees, covering water and gas, sewerage and burial, and in Scotland poorhouses and district asylums, venereal diseases, and the welfare of the blind; but of all joint boards those which have to do with hospitals are most numerous, totalling 212 in England and Wales.

LARYNGEAL SURGERY

Diseases and Injuries of the Larynx. A Textbook for Students and Practitioners. Chevalier Jackson, M.D., Sc.D., F.A.C.S., and Chevalier L. Jackson, M.D., M.Sc., F.A.C.S. Second edition. (Pp. 633; illustrated. 36s.) New York and London: The Macmillan Company, 1942.

A second edition of *The Larynx and its Diseases*, by Chevalier Jackson and Chevalier L. Jackson, has been issued under the title *Diseases and Injuries of the Larynx*. The present edition does not differ in essentials from the first (reviewed in these columns on Oct. 16, 1937), but is longer because a chapter on war surgery of the larynx has been added. This is rather out of keeping with the rest of the book, which is almost entirely based on Jacksonian observation and experience, while the new chapter does not give any indication of personal experience in the surgery of war, except in the matter of the effects of poison gas, which so far has not been employed in the present conflict. The authors have changed their views to some extent on the surgical treatment of cancer of the larynx, but they still give a quite inadequate picture of what can be accomplished in the surgical treatment of the intrinsic variety of the disease, and the statement that in the "extrinsic type of cancer surgery is worse than useless" ignores what has been accomplished by others, and coming from such an authority must hinder any attempts at progress in this direction. In all other aspects of laryngeal surgery the book reveals what can be done by patient endeavour often extended over long periods, and how great is the debt of laryngology to endoscopy as practised and taught in the Jacksonian clinic. The book is of more value as a picture of how a great master of his art sees it and practises it than as the complete textbook at which he has aimed, for there is no attempt to keep abreast of recent

literature; for the authors the Jacksonian practice and tradition are all-sufficient. It constitutes, however, a valuable record of magnificent work in laryngology, which no laryngologist can neglect.

AFTER-CARE AND REHABILITATION

After-Care and Rehabilitation. By Various Authors. (Pp. 128. 8s. 6d.) London: The Practitioner in conjunction with Eyre and Spottiswoode.

This is the ninth of the series of "Practitioner" booklets. It deals with every aspect of after-care and rehabilitation in a comprehensive and easily readable form. There are twelve articles dealing with post-operative care, with the after-care of various medical conditions, and with rehabilitation after head injuries, fractures, and amputations. There is also a chapter on physiotherapy in post-operative convalescence, and a chapter on occupational therapy. All these papers are well and clearly written by experts, and if there is any fault to find with this booklet it is that there has been a certain amount of overlapping in the chapters on post-operative care.

One of the most useful and practical features of the book is the chapter by Dr. Geoffrey Evans on rehabilitation in patients confined to bed, in which is given some extremely practical and detailed advice on the types of exercises to be employed in these cases. All the chapters are of a high standard, and the book should have a very wide appeal. Prof. F. R. Fraser sums up the present position in an excellently written foreword urging a more positive and planned attitude on the part of the profession towards what used to be rather vaguely described as "convalescence."

Notes on Books

Volume 67 of the *Transactions of the American Gynecological Society*, for the year 1942, is edited by Dr. HOWARD C. TAYLOR and published at St. Louis by the C. V. Mosby Company. The papers in this volume are without exception reprinted from the *American Journal of Obstetrics and Gynecology*. The "In Memoriam" section includes an appreciation of Dr. Herbert R. Spencer, an honorary Fellow of the Society, by his friend Dr. George Gray Ward, who met him on various yearly visits to London.

E. B. UVAROV'S *Dictionary of Science* (Penguin Books; 9d.) is a work which is remarkable both for the wealth of matter included and for the clarity with which the subjects are explained. Hardly a word is missing in it that may occur in scientific literature, and wherever an enlargement of the given explanation may be desired a further store of information will be found under a kindred title to which a cross-reference is given. Complete, compact, and lucid, this volume is worth a bookbinder's finish.

Starch and its Derivatives (Chapman and Hall; 36s.), by J. A. RADLEY, is in essence a textbook of applied chemistry having starch for the centre of its interest. Starch itself presents a wide field of study in pure chemistry; it has many and diverse uses in industry and in the arts, and is the raw material for making a variety of economic products. There is here a large field for both pure and applied chemistry, and there have been extensive developments in both domains. These developments are here fully and ably described.

Preparations and Appliances

DEVICE FOR THE PROTECTION OF THE EXPOSED CORNEA

.... FREDERICK RIDLEY, F.R.C.S., writes:

From time to time cases are seen in which the cornea is exposed owing to loss of tissue or cicatricial contraction of the lids following burns. A case recently admitted to an E.M.S. hospital presented unusual difficulties. An extensive area of skin around the eye and including both lids was involved in a third-degree burn complicated by gross sepsis. The lids retracted rapidly, exposing the cornea, which became oedematous and threatened to ulcerate. The raw area round the eye would not tolerate any appliance, the skin condition did not permit of immediate grafting, and lid suture has always failed in this type of case.

The problem was tackled by means of the appliance illustrated. A dental cap splint with an extra-oral extension bar attached by means of screws and plates was fitted, and to this bar a second rod carrying a shield to fill in the palpebral aper-

ture was attached by means of a universal joint of the Clouste Walker pattern, provided with a locking screw. A Zeel impression of the palpebral aperture and exposed cornea a conjunctiva was taken, using a suitably curved and sharp small metal tray. Artificial stone moulds were prepared a the shield processed in acrylic resin in the usual way. The carrying the shield was cast integrally with it, as is shown the illustration. The sharp edges of the shield were removed the tips corresponding to the canthi rounded off, and the ocu-

surface lined with a thin layer of No. 8 gauge dental casting wax. Experience has shown that this wax is very well tolerated in contact with the cornea. If the shield shows a pronounced corneal bulge it is desirable to remove this by polishing or to fill the hollow with wax, as the cornea moves freely over the ocular surface of the shield.

The apparatus was made and fitted within six hours and proved comfortable in use, being adjusted so that the shield is just in contact with the cornea. As the cicatricial contraction increased, the appliance was built up with wax to maintain approximation to the lid edges. After ten days a larger shield was made, and this was subsequently built up in the same way. Apart from removal each day to irrigate and inspect the eye, the apparatus was worn day and night for seventeen days without discomfort. At the end of that time the skin was ready for grafting. Apart from a little injection of the conjunctiva no reaction was seen. The corneal oedema cleared up in a few hours and no further anxiety was experienced.

It is hoped that this apparatus, which can be prepared quickly in the larger dental units, may prove of value in the care of this rare but often disastrous condition.

My thanks are due to the staff of the dental department of the Maxillo-Facial Unit, East Grinstead, for their co-operation in planning and preparing the apparatus.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY AUGUST 28 1943

THE PENICILLIN POSITION

We print on p. 274 a statement on penicillin from the Medical Research Council, the object of which is evidently to warn the profession that supplies of this substance are unlikely to be available for general use for some considerable time—possibly until the end of the war, since Service needs will certainly be met first as long as it continues. The amount available at present is so small as to make it inadvisable to advertise the names of centres where its use is being studied, lest they should be overwhelmed with requests to treat cases which can only be declined. The object of the clinical work going on at present is indeed not so much to treat conditions already known to be amenable to penicillin treatment as to explore its further possibilities. Something will doubtless be heard shortly of the further progress of this work, and in the meantime readers of this *Journal* may like to be reminded of the main facts which are already known, especially since the subject has attracted a good deal of popular interest.

Penicillin is an antibacterial substance with a highly selective action formed by the mould *Penicillium notatum* and easily obtained in crude form in filtrates of cultures of this mould. Discovered by Fleming as long ago as 1929, it was restudied by Florey and his colleagues at Oxford after the war began, and by them a method was devised of extracting and partially purifying it, the result being an antiseptic having unheard-of properties. At this stage their main report,¹ which is still the chief exposition of its subject, made it clear that penicillin has all the qualities of the ideal antiseptic: an enormous capacity for inhibiting the growth of certain bacteria, an efficiency unimpaired by environment—neither serum, blood, nor pus detracting from its effect—and, above all, an almost complete freedom from toxicity to mammalian cells. It is upon this rock that every other "biological antiseptic" has foundered. Gramicidin, for example, the bactericidal substance isolated by Dubos from a soil bacillus now identified as *B. brevis*, is highly toxic to animals and clearly unsuitable for systemic use, although it may have limited uses as a local application. The same is true of actinomycin,² proactinomycin,³ of the unnamed substance⁴ extracted from *Penicillium claviforme*, and probably of streptothricin.⁵ These are only a few of the better known antibacterial products which have been isolated from various fungi in a systematic search to which the success of penicillin was the chief incentive. Among these studies, those of Raistrick and his colleagues⁶ have gone furthest, since these workers not only examined very many species of *Penicillium* and *Aspergillus* and identified a large number yielding antibacterial products, but determined the chemical constitution of some of the active substances and even synthesized them. Many of these other mould pro-

ducts are obtainable in large yields, stable and easily purified; in some cases they act on a wider range of bacteria than penicillin, including Gram-negative species, but none has so powerful an effect on Gram-positive cocci, and none so far as present information goes is non-toxic; those which have been studied from this standpoint are decidedly the reverse. The search for something else as good as penicillin but perhaps more easily produced has therefore failed, as have efforts to synthesize it.

The product used by the Oxford workers in 1941 was still grossly impure, having an activity of only about 40 Florey units per mg. A year later⁷ such further purification had been achieved that the activity was raised even to 500 units per mg., but this entailed serious loss, only about 15% of the active constituent surviving. This product completely inhibited the growth of *Staph. aureus* in dilutions as high as 1 in 30,000,000, but was even less toxic than its cruder predecessor: leucocytes survived exposure to a 1% solution. It was with penicillin thus further purified, although not always of the maximum potency attainable at such expense, that the further clinical trials were made which M. E. and H. W. Florey⁸ described at length a few months ago. Systemic treatment was given in 13 cases, the continuous intravenous drip originally advocated being largely replaced by three-hourly intramuscular injections: 10 of these cases were of severe staphylococcal infections, 6 having positive blood cultures, and all recovered. A case of streptococcal meningitis resistant to sulphonamide treatment was given penicillin intrathecally as well as intramuscularly, and recovered. A favourable effect was obtained in a case of pulmonary actinomycosis, and no lasting effect at all in a case of endocarditis lenta due to *Strep. viridans*. Except in the presence of renal failure,⁹ which might from this standpoint be actually an asset, penicillin is rapidly excreted by the kidney, and systemic treatment therefore demands frequently repeated doses often rising to a total of 2,000,000 units before recovery is assured. Contrasted with this lavish expenditure is the economy with which effects can be obtained by local application, the other form of treatment described in the Floreys' paper. Local sepsis, in the form of accidental wounds, mastoid disease, and chronic sinuses, was successfully treated by introducing comparatively small amounts of penicillin, as were various superficial infections of the eye. Colebrook and his colleagues¹⁰ have also found penicillin in the form of a cream highly effective in eliminating infection from burns.

The possible uses of penicillin have to be thought of in terms of the infecting organism. Pride of place goes to *Staph. aureus*, not only because of its extreme susceptibility to penicillin, but because it is far less controllable by sulphonamides than the other pyogenic cocci. That staphylococcal septicaemia is curable with penicillin is well established, and for this condition more than any other it is being most urgently demanded. It has also been used successfully in osteomyelitis, and in staphylococcal infection of wounds, burns, and the eye. Haemolytic streptococci and pneumococci are also susceptible to penicillin, but, since sulphonamide treatment for their various infections is usually effective, penicillin need only be considered when this fails. McKee and Rake¹¹ have shown that sulphadiazine-resistant strains of pneumococci respond normally to penicillin; the mode of action of the two substances is undoubtedly quite different, and resistance to one is an indication for treatment with the other. What else penicillin may conceivably be found capable of may be guessed

¹ *Lancet*, 1941, 2, 177.² Waksman, S. A., and Woodruff, H. B., *J. Bact.*, 1941, 42, 231.³ Gardner, A. D., and Chain, E., *Brit. J. exp. Path.*, 1942, 23, 123.⁴ Chain, E., Florey, H. W., and Jennings, M. A., *ibid.*, p. 232.⁵ Waksman, S. A., and Woodruff, H. B., *Proc. Soc. exp. Biol.*, N.Y., 1942, 43, 207.⁶ *Chem. and Ind.*, 1941, 60, 528; 1942, 61, 22, 48, 128.⁷ Florey, H. W., and Jennings, M. A., *Brit. J. exp. Path.*, 1942, 23, 120.⁸ *Lancet*, 1943, 1, 387.⁹ Rammelkamp, C. H., and Keefers, C. S., *J. clin. Invest.*, 1943, 22, 425.¹⁰ *Lancet*, 1943, 1, 605.¹¹ *Proc. Soc. exp. Biol.*, N.Y., 1942, 51, 275.

from the list of bacteriostatic titres for many species of bacteria in the original main paper by the Oxford team. Its action on tubercle bacilli, on the intestinal Gram-negative bacilli, and on *H. influenzae* is negligible. On the other hand it has a powerful action on the gas-gangrene group, which has received experimental confirmation in the studies of J. McIntosh and W. R. Selbie¹² on *Cl. welchii* infection in mice. It will thus be seen that all the major infections to be feared in battle wounds come within the theoretical scope of penicillin treatment, although its practical efficacy has yet to be proved and the best methods of application have yet to be devised. That the Services have a prior claim on available supplies no one is likely to dispute. Among other bacteria high up on the list of susceptible species are the anthrax bacillus, the gonococcus, and the meningococcus. This brief review of what is known and what fields remain to be explored will give some idea of the magnitude of the task which lies before those entrusted with prosecuting this investigation. Penicillin is in some ways the most remarkable of all the chemotherapeutic agents which have come to light in such profusion during the past eight years, and it is tantalizing that supply difficulties should bar its rapid exploitation. Where it most clearly excels the sulphonamides is in the local treatment of established sepsis; and the field for such treatment is enormous, especially in time of war. Whether to employ a given stock in the rapid restoration to health of many patients suffering from disabling but not dangerous infections, or to use it to save a single life endangered by septicaemia, must be a difficult decision to make, and is perhaps not the only dilemma which will arise as the further possibilities of penicillin treatment become known.

TUBERCULOSIS IN CHILDHOOD

Of all infectious diseases which are liable to spread in time of war, only tuberculosis has gained serious impetus in this country. That it now constitutes a grave problem everyone must be aware; but it is thought of mainly in terms of adult phthisis, and the effects in children deserve much more attention than they have so far received. Readers of this *Journal* may recall that the issue in which we published an abstract of the report of the M.R.C. Committee on Tuberculosis in Wartime¹³ also contained an article¹⁴ by Dr. Allen Daley, the Chief Medical Officer to the L.C.C., and Mr. B. Benjamin of the Statistical Branch. This paper analysed the trend of tuberculosis in London during 1938-41 and revealed an alarming increase of the disease in children: new cases of both pulmonary and non-pulmonary tuberculosis and deaths from the former all showed increases varying from 177 to 442% in 1941 compared with 1938; the greatest increases were in the youngest age group (0-4 years), but at 5-14 years they were also far greater than among adults. Whether even these figures, which are based on notifications, fully represent what is going on may be doubted after reading the account by Dr. Marcia Hall (*Lancet*, 1943, 2, 35) of her study of tuberculosis among evacuated children in East Sussex. The social change with which this study is concerned is evacuation and billeting, but it draws an alarming picture of the infectivity of the disease among children and well illustrates the consequences of their exposure to infection, which must everywhere be accentuated by an increase in adult disease. The method employed was the thorough examination of all home and school contacts of known cases, including radiography, estimation of the sedimentation rate,

tuberculin skin tests, and in some cases examination of gastric contents for tubercle bacilli. Two evacuated children found to be suffering from the disease had infected a total of 15 other children in their billets at school classes; both had been suspected of tuberculosis in London before their evacuation, but no note had been sent to the tuberculosis officer of the reception area. Of 6 children billeted with a foster-mother who herself had pulmonary tuberculosis, 5 became infected and in their turn transmitted the infection to a number of school contacts. Several of the children involved in these melancholy episodes have died, and a number of others are undergoing institutional treatment.

The danger to children of contact with open pulmonary tuberculosis cannot be over-emphasized. That they are much more readily infected than adults would be more clearly understood if the disease in them did not assume a form which is notoriously difficult to diagnose. Without radiographic and laboratory facilities its diagnosis is often little more than guesswork. The early recognition of tuberculosis in childhood is the subject of a report by a sub-committee of the British Paediatric Association which has been circulated to interested persons and institutions and deserves a wider publicity. This report recommends a series of far-reaching measures to remedy what is at present a serious defect in our public health system. The first need is the examination of all child contacts down to infancy of known cases of pulmonary tuberculosis, and, conversely, a search among adult contacts for the source of infection when a child develops the disease—this in order to prevent the infection of further children. There should be some mechanism whereby children suffering from erythema nodosum or phlyctenular conjunctivitis can be brought to the notice of the tuberculosis officer. Special clinics are required for the examination of children, not only equipped with all necessary diagnostic facilities but staffed by those with paediatric experience. Finally, there is a serious lack of facilities for institutional treatment: children should not in general be sent to adult sanatoria. These are the main points in a document which forms a serious indictment. The effect on children of the present increase in adult pulmonary tuberculosis is one of the worst features of the situation as we see it now, and such steps as may now be possible for dealing with it deserve earnest attention.

THE ERGOT ALKALOIDS AND INVOLUTION OF THE UTERUS

The discovery and isolation of a new alkaloid of ergot—ergometrine—were foreshadowed by Chassar Moir in these columns in 1932¹ and described in detail by H. W. Dudley and Chassar Moir in 1935.² Since then the rapid and strong oxytocic action of ergometrine has been amply confirmed by its widespread clinical application. Equal in speed and efficiency to extracts of posterior pituitary for the control of post-partum atony and haemorrhage, it possesses advantages over such extracts in that it is non-toxic and has no effect on the vascular or autonomic nervous systems. These advantages are not yet appreciated by all who practise obstetrics, and cases of "pituitrin shock," often mistaken for "obstetric shock," still occur. The introduction of this ergot alkaloid (also isolated and described by independent workers in Switzerland and the U.S.A. in 1935) was unfortunately clouded by a controversy over nomenclature, and it has been variously called "ergobasin," "ergotocin," "ergotrate," "ergostetrine," "ergocline," and "ergonovine." So far as this country is con-

¹² *Lancet*, 1942, 2, 750.

¹³ *British Medical Journal*, 1942, 2, 436.

¹⁴ *Ibid.*, p. 417.

¹ *British Medical Journal*, 1932, 1, 1119.

² *Ibid.*, 1935, 1, 520.

cerned, however, confusion has to a large extent been avoided by the ready and wide acceptance of the term "ergometrine," first suggested by its discoverers.

In a recent paper³ Chassar Moir and Scott Russell discuss the use of ergometrine and ergotamine during the puerperium. In a large series of cases the rate of involution of the uterus was assessed by careful observation of the height of the fundus and of the amount and character of the lochia. Their findings, in contrast with the results of similar if less carefully controlled investigations by other workers, go to show that neither of these ergot alkaloids is beneficial to the process of involution. Study of the problem is hampered by incomplete knowledge of the physiology of involution. The oldest view—that the muscle undergoes fatty degeneration and a large proportion of the fibres disappear—is no longer accepted. The process is one of atrophy, and is said to represent the most rapid type of atrophy known to occur in any tissue under either physiological or pathological conditions. The muscle fibres are reduced in size with loss of cytoplasm, but it is doubtful whether they are to any extent reduced in number. If this is the result of ischaemia brought about by the contraction and retraction of the uterine muscle fibres, then ergot should assist involution. But if the hypertrophy of the uterus during pregnancy is the result of the presence of large amounts of oestrogen in circulation and the mechanical stimulus of the products of conception, then it is reasonable to assume that the puerperal atrophy is the result of the withdrawal of such factors. In such a case ergot, by increasing the rate and amplitude of contractions to the extent of inducing spasm, could not assist involution, but might well have an adverse effect by hindering the absorption of the products of autolysis. The scientific basis of the traditional ergot therapy in the puerperium is certainly open to question, and the latest clinical observations indicate that it does not facilitate involution.

Ergot alkaloids are often advised in the treatment of uterine puerperal infection, but, again, Chassar Moir and Scott Russell record no decrease in the morbidity rate in patients given ergometrine and ergotamine. They argue, moreover, that, as infection elsewhere in the body is treated by resting the infected tissue, it is unreasonable to induce activity in a uterus that is infected. There is, however, a place for ergometrine in the treatment of those cases, not necessarily infected, in which the lochial discharge is partly retained in the uterus. In these days, when the supply of ergot and its alkaloids is limited and should be conserved, those clinicians who still prescribe them as a routine in the puerperium would do well to reconsider whether they should continue a practice which, if not harmful, is of doubtful value and is certainly wasteful.

CLINICAL BIOTIN DEFICIENCY

Biotin (formerly known as vitamin H and coenzyme R) is the latest vitamin to be synthesized. This was done last May by Harris and his colleagues in America,⁴ confirming the formula assigned to the vitamin last year by du Vigneaud and his collaborators, who concluded that it was a carboxylic acid with a nitrogen-substituted cyclic urea grouping and sulphur in a thio-ether linkage.^{5,6} The existence in raw egg-white of avidin—a protein which forms a complex with biotin—has been known for some time. Oral administration of large amounts of dried egg-white to rats produces a deficiency syndrome characterized by an exfoliative dermatitis, hyperkeratosis, alopecia, loss of

weight, and spasticity. This condition, known as egg white injury, is due to the avidin forming a complex with the biotin of the diet and preventing its absorption. We referred in these columns last year⁷ to the work of Sydenstricker and his colleagues,^{8,9} who claim to have induced biotin deficiency in human beings by the administration of large quantities of raw or dried egg-white. The subjects of the test suffered from a scaly dermatitis, ashen-grey pallor, tongue lesions, paraesthesiae, nausea and changes in the blood picture. The experiment afforded clear evidence that biotin is an essential food factor for man. In this connexion Williams's study of an old retired Italian labourer who had suffered from an exfoliative dermatitis and mild conjunctivitis for several years is of interest.¹⁰ There was no history of medication or exposure to chemicals to account for the rash, but the dietary history was significant. Since adolescence the patient had been extremely fond of raw eggs, and in order to get enough he had deserted his family so that he could run a chicken farm. His consumption of raw eggs ran into six dozen a week. He was not to be expected to eat regular meals on top of this, but what was unexpected was the fact that he drank one to four quarts of wine daily. His choice of foods was narrow and excluded good sources of biotin (milk, meat, liver). The skin lesion, which was also studied by biopsy, did not correspond to that due to deficiency of nicotinic acid, riboflavin, pantothenic acid, or pyridoxin (vitamin B₆), but closely resembled that seen in animal deficient in biotin. Before treatment the serum biotin was low. After the patient had been in hospital for a fortnight, during which time he received a liberal hospital diet and injections of the methyl ester of biotin, the dermatitis largely disappeared and the serum biotin returned to normal. This would appear to be the first recorded case of clinical biotin deficiency: Sydenstricker's patients were volunteers on an experimental diet. Biotin deficiency as a result of the action of avidin is unlikely in egg-depleted England. In any case the avidin binds biotin only when the eggs are eaten raw or dried and uncooked, and even then they would have to be taken for a long time. Williams's patient ate large quantities of raw eggs for years before deficiency symptoms appeared. It is not surprising, therefore, that Rhoads and Abels¹¹ could not induce a biotin deficiency in patients suffering from cancer—tumour tissue is rich in biotin, which is possibly essential for its growth—by feeding 375 g. of raw egg-white and 165 g. of dried egg-white daily for thirty weeks.

Kögl and Tönnis,¹² who first isolated biotin, obtained only a milligramme from a ton of dried egg-yolk. Now that it has been synthesized it should be available in quantities which will permit further investigation of its function in human nutrition.

VITAMIN C AND COOKING

Thanks to propaganda on the part of the Ministry of Food the nation has begun to worry about its vitamin C, and so imbued has it become with notions about rates of destruction and such-like that all sense of proportion is being lost. There is a popular idea nowadays, for instance, that if vegetables are left over from dinner it is useless to keep them and reheat them, for they will have lost all their nourishment; that they might just as well be thrown away. This idea is erroneous. The reheated vegetables will provide as many calories as when they were freshly cooked

(more if they are fried in a little fat), and they will contain just as much protein and minerals. "Save food" is the first rule in wartime cooking, and it is foolish to throw away good food just because it may have lost some of its ascorbic acid. This vitamin, however, has quite rightly been given special attention, because it is the dietary essential most likely to be deficient in wartime diets. Miss M. Olliver¹ has recently published the results of her extensive investigations into the vitamin C in fruits and vegetables, and the effects of storing and cooking them in different ways. Of common home-grown fruits, blackcurrants and strawberries contain more vitamin C than oranges or lemons. Other bush fruits with edible pips such as gooseberries, loganberries, raspberries, blackberries, and also tomatoes are moderately good sources (20 to 40 mg. per 100 g.), while apples, pears, and stone fruits such as plums and cherries contain very little (less than 10 mg. per 100 g.). When any of these fruits are stewed ascorbic acid is extracted into the juice, but as this is generally eaten there is little or no loss of the vitamin, or indeed of any of the constituents—only a dilution with the cooking water. Jams made from these fruits also retain all the vitamin C of the original fruit, but it is diluted with sugar and water. Blackcurrant jam is a better source of vitamin C than raw lemons or grapefruit; plum jam contains practically none.

Storage has a bad effect on vitamin C. Green leafy vegetables and peas in the pod, which when freshly gathered are an excellent source, lose about 10% of their ascorbic acid every day they are stored after harvesting. Root vegetables do not lose vitamin C so rapidly, but losses on storage cannot be ignored, because roots are often eaten many months after they are lifted. Potatoes, for example, contain 16 mg. ascorbic acid per 100 g. when they are freshly dug in August and September. By March they contain only 2 mg. per 100 g.

When vegetables are boiled the soluble constituents diffuse out into the cooking water, which the English cook or housewife generally throws away, and the more soluble the constituent the more will be dissolved out in this way. The extent of the loss also depends upon the volume of the cooking water and the time of cooking, but more still upon the surface area of the pieces of vegetables in relation to their size. Green leafy vegetables with a large surface area may lose 80 to 90% of their soluble constituents, while potatoes only about 20%. The addition of salt and soda to the cooking water seems to make no appreciable difference to the loss. So far as the minerals are concerned, these losses are of little importance. The soluble elements, Na, K, and Cl, are always plentiful in ordinary diets. Ca and Fe, which are more likely to be deficient, are relatively insoluble, and conservative methods of cooking are unlikely² to increase the daily intake by more than about 3%. Vitamin C, however, is soluble and it is scarce, and vegetables are now our chief source during most of the year. Every effort, therefore, should be made to preserve it. Two years ago a note was drawn up by the Accessory Food Factors Committee of the M.R.C.³ suggesting how this should be done, and the chief points were these. Obtain vegetables as fresh as possible and keep in a cool damp place. Use the smallest possible amount of water for cooking, and have it boiling before adding the vegetables. Cook vegetables no longer than is necessary to make them tender, and serve them directly they are cooked. Use the cooking water for soups and gravies. But—even if these rules have been broken—the vegetables should not be thrown away.

CLEANING MILK BOTTLES

Among the precautions necessary to ensure a safe milk supply the condition of the bottles into which it is filled must clearly be taken into account. Contaminated bottles have in fact been known to cause outbreaks of enteric fever though this mode of infection is much less common than contamination of the milk itself before bottling. It is generally agreed that the single-service carton is the ideal container for milk, but its widespread adoption is not only quite impracticable now but unlikely for many years, since much capital in the dairying industry is sunk in bottling plants. A study of methods now in use for cleaning and sterilizing milk bottles was carried out during 1937-9: the request of the Ministry of Health by Betty C. Hobbs and G. S. Wilson, and a condensed version of their report which is itself a formidable document containing much valuable information, has now been published. Their first task was to devise a method for determining the bacterial content of washed milk bottles, and the method chosen from among several studied is likely to be generally adopted: it consists in rinsing the bottle with sterile fluid of which aliquot portions are plated for bacterial counts. The standard suggested is a count of not more than 600 colonies per pint bottle, or approximately 1 per c.c.m. capacity. This method was used for the examination of bottles from 105 bottle-washing plants in Greater London which were of 26 different types. Generally speaking, the lowest counts were given by bottles from large plants employing detergents, the straight-through being better than the rotary type, and spraying being better than soaking in the detergent. Steam sterilization gave less satisfactory results, and hand-washing much the highest counts of all. It seems clear that combined cleaning and disinfection by detergents such as caustic soda, the disinfectant action of which has recently been exhaustively studied by these authors,² is preferable to steam sterilization. Bottles so treated are at that stage sterile or nearly so, yet the final product may be heavily contaminated; and, indeed, the large majority of those examined did not conform to the standard proposed. This was found to be due to recirculated water used for rinsing, this water being itself so heavily contaminated that bacterial growth evidently proceeded in it. This difficulty can be overcome by using hot water, but the objection to this is that the bottles need to be cooled before filling. An alternative is the use of chlorinated rinse water, but this method demands accurate control such as it is not likely always to receive, and the authors accordingly do not recommend it. Their remedy which deserves serious consideration in the future design of bottle-washing plants, is to follow rinsing with hot water by external washing only with recirculated cooling water and a final rinse, both external and internal, with a cold spray direct from the main. Apart from the actual danger of using imperfectly sterilized bottles, which may stultify all efforts to improve the bacterial quality of the milk itself, this question must have an important bearing on keeping quality. It is thus a subsidiary aspect of the milk problem which deserves more attention than it has so far received. The need for cooling bottles before filling would of course be removed were the milk to be pasteurized in bottle, a system which in theory at least has much to be said for it. The possibility of recontamination after pasteurization is not only a frequently advanced objection to reliance on this process but a practical difficulty inherent in any system which involves the further manipulation and transfer of a sterilized product.

CHILD CARE IN A NATIONAL HEALTH SERVICE*

BY

GEORGE F. BUCHAN, M.D., F.R.C.P., D.P.H.

Medical Officer of Health, Willesden

It is difficult to say precisely when the child welfare movement began, but we do know that it initiated with voluntary agencies. At the outset I should pay my tribute to the pioneer work for the care of children which has been carried on by the component bodies of the National Council for Maternity and Child Welfare. Many societies over a period of years have interested themselves in and developed some particular phase of child care. These agencies for a time worked in isolation, but the need for co-ordination of their activities became apparent and resulted in the establishment of the National Council, under whose auspices we meet to-day. If the pioneer work of these voluntary bodies did nothing else it stirred the public at the end of last century to a realization of two facts—that the birth rate was falling, and that the infantile mortality rate remained at a high level. Thought begat action, with the result that since the beginning of the present century progressive provision has been made for infant care, and there now exists throughout the country a vast network of child welfare centres and other and allied provision, both municipal and voluntary, for the care and nurture of the child.

All this provision has been made with the view of securing the health of the child, and great good work has been achieved—notably a fall in the infantile mortality rate in 1942 to 49, as compared with 151 in 1901. Whether it is as the result of this splendid achievement or otherwise, the people generally are demanding health not only for the child but also for themselves, and it is my privilege to put before you the essential elements of a national health service and child care within it.

Concept of a National Health Service

Primarily a national health service must be based on the conception of the maintenance of the health of every individual from the cradle to the grave, and the measure of disease within such a service must be regarded as the measure of its failure. Health includes not only bodily health but mental health. Health is dependent on many circumstances. How can you expect to rear a healthy race if fathers or mothers are themselves suffering from transmissible diseases? Can the health of any family be at a level where there is not sufficient food or clothing? Is it to be expected that people can be at the top of their form if they are living under insanitary conditions in damp and overcrowded houses? Is the smoky atmosphere of our towns conducive to healthy lungs and a bright and cheerful outlook on life? Can we separate good health from good environmental conditions—from the conditions under which we live at home, from the conditions under which we work at the office or in the factory, or the child in the school or the nursery?

The doctor in a national health service must be a real family doctor who will know and appreciate all the various factors bearing on the health of the family or any individual member of it. He not only must be able to detect and cure disease but must realize the importance of the hereditary influences, environmental conditions, and social circumstances affecting health. The doctor must indeed be, more than ever before, the counsellor and friend of the people and assume responsibility for the achievement of health, which is the primary aim of a national health service.

A comprehensive health service has many components. It includes a medical service—consisting of general practitioners, public health practitioners, consultants, and specialists, working at and from well-equipped health centres and hospitals, visiting the people in their homes, and looking after their health and welfare in the factories and their work-places. Such a service further includes the provision of the necessary auxiliary services—e.g., health visiting, nursing, midwifery, sanitary, and ambulance services. A dental service is also a necessity. It

will be appreciated that a service of this character is vast and complex and, in the opinion of many well qualified to judge, requires a Minister of Cabinet rank as its administrative head, with a central department dealing only with matters that have a bearing on health. Locally such a service must be conducted in an area of suitable size under a unified control. Providing these desiderata are secured, it seems to me that a national health service will rapidly make harmonious progress towards better health. All health work will be co-ordinated, and the best means of attacking health problems will be devised after full consultation with all concerned.

I want to see the health, medical, and ancillary services appropriately co-ordinated in an area of adequate resources. Particularly I want to see in operation a scheme whereby every general medical practitioner, every public health medical practitioner, every specialist, and every consultant throughout the whole of the country will be constantly thinking about health and working together as one gigantic team for the health of the community. I am satisfied that the health of the community as a whole will then soon show an improvement as spectacular as that achieved for the child by the child welfare movement.

A Child's Charter

With the establishment, however, of a national health service we do not want any lag in the improvement of child health, and it would appear to be necessary to state what provisions should be made for child care in such a service. Here is the Child's Charter I would formulate. It contains 12 Articles of Faith.

1. The child must be well born and free from inherited disease.
2. The child must be assured of a good environment and a happy home.
3. There must be adequate children's allowances.
4. The pregnant woman must be fully cared for medically and socially, so that the child is born well and strong.
5. Home helps and convalescent homes should be available before, during, or after confinement as necessary.
6. The mother must be enabled to devote herself to her child for a period of three years after birth.
7. The child must receive an adequate diet.
8. The child must be under regular medical supervision.
9. Nurseries should be provided in which mothers may leave their children under 3 years for, say, 3 or 4 hours at a time, while they do their housework or shopping or have rest.
10. Nursery schools should be available for children over 3 years.
11. Hostels should be provided for children whose mothers are in hospital for confinement or illness.
12. Approved foster mothers should be available for approved cases.

In connexion with child care it should always be borne in mind that the natural agencies for the care and upbringing of a child are the family and the home, and that generally they are the best and that everything should be done to preserve these links. It may be, however, that this is not possible in some cases and that a foster mother has to be substituted. If this is so, then certain conditions should be required: (a) The decision to foster out a child should not be left entirely to the parent or guardian as at present. It should be necessary for the consent of the welfare authority to be obtained. (b) Applications for placing children with foster mothers should be made by the mothers to the welfare authority, and the mothers should be required to keep in touch with the welfare authority. (c) It is essential that foster mothers should be assured of regular and sufficient payment for the proper care of the child; to this end the payments to foster mothers should be made directly by the welfare authority to the foster mothers. (d) Foster mothers should be licensed by the welfare authority after a probationary period of, say, 1 year. (e) The child-protection visitors of the welfare authority should keep foster mothers under supervision and see that a reasonable standard of living is maintained; if foster mothers are paid by the welfare authority a proper standard can be required.

These are my 12 Articles for progressive improvement in child care and health. They include medical elements, but are by no means wholly medical. I cannot insist on this too strongly, because there are many who believe that a hospital policy is a health policy. It is the duty of the doctor to

* An address given to the National Conference on Maternity and Child Welfare, London, on July 9, 1943. (Abridged for publication.)

postpone the event of death at any age. Recent discoveries and hospital provision enable considerable patching to be done, with resulting prolongation of life. But while such work is laudable and necessary it can never be the essential basis of health. We do not want patching. We do not want to be crippled and obtain spasmodic relief for longer or shorter intervals after a period of treatment. We want health. We want and earnestly desire that the child shall be well born and shall remain well. We do not want the child to whom we have given so much care to develop into a hospital-visiting adult. We desire that all members of the community shall have the same consideration for the maintenance and improvement of their health as has been given to the infant with such conspicuous success. If the national health service in the making says down health as its aim, and makes provision so that the aim can be reached easily and simply under a single direction regardless of self-interest or vested interests, then I feel sure that rapid progress towards national health will be made.

6. *Abdomens*.—Nothing has made such an advance, at least as regards early saving of lives. Sew the tears in small bowel: exteriorize ones in the large. Get a Ryle's tube down and keep suction going with a blood transfusion apparatus (with water) to do the work. Then saline glucose, intravenous. Both of these for 4-5 days. And gr. 1/6 or 1/4 of morphine 4-hourly. Never despair of an abdomen.

7. *Heads*.—Shave, dust sulphanilamide, and leave the head units, with the diathermy and sucker, to do the rest.

The handy book I carry is *Treves's Student's Handbook of Surgical Operations*. For the things that worry—anatomical points like ligating the posterior tibial, etc.—are all there!

There, dear boy, forward surgery in a nutshell—and for nothing—by one who *should* know. But I'll write again soon with real news. This is just so as you won't worry if you are called up. If you are, come this way.

A NOTE ON SURGERY IN THE EIGHTH ARMY

The note published below was written by a surgeon in the 8th Army in the closing stages of the Tunisian campaign. It was written on a letter-card to a colleague at home who, about to go into the Army as a surgeon, wanted to have first-hand information on war surgery at the Front. We have not tampered with the author's idiom.

1. *Débridement*.—All my eye! Means excision of far too much. Skin edges rarely need excision. Dead tissue only is removed, and the wound, including deep fascia if necessary, opened up enough to allow adequate drainage and to relieve tension if present. This we call "wound trimming." Clean through-and-through wounds with a bullet, unless tension be present, are left alone except for sulphonamide dusting, which is done in all. Then lay a vaseline gauze dressing on; don't make it into a plug!

2. *Amputations*.—There are no sites of election in war surgery. You save all you can, as there is invariable sepsis in forward areas, and this means subsequent loss. So it usually has to be done again, to suit the instrument maker, many months later. A thin layer of sulphanilamide vaseline gauze is put over the muscle and some of the stump, and then the flaps approximated with not more than 3 stitches. The results are excellent. Don't worry about types of flaps: save all you can.

3. *Plaster-of-Paris*.—Always split if being evacuated within a week (I speak of fresh cases), and also for evacuation a lightly padded plaster is better than an unpadded. Evacuation, especially on our long lines of communication, knocks hades out of patients in all sorts of ways. Limb swelling is one of them.

4. *Fractures*.—Use your common sense. The way a fractured femur gets to the base (apart from initial treatment—see excellent description in R.A.M.C. manual of training) is in what is called a Tobruk plaster. Skin extension, plaster-of-Paris round the leg and split, Thomas splint on top of this, with pads of wool between the leg and the irons at the knee level to steady the extension to the end of the Thomas. Then two cuffs of plaster-of-Paris, right round splint and everything, in mid-thigh and mid-leg, either padding or splitting the cuff, again to prevent circulatory disasters.

The fractured humerus is more difficult to immobilize for a long journey. Generally it is done by a thoraco-brachial plaster. This explains itself. One big point is to keep the tip of the elbow forward from rubbing on the crest of the ilium. Any fracture of os calcis or astragalus is followed by immense swelling of the foot. Pad the plaster very well. Indeed, only put the plaster on to keep the padding on!

5. *Chest Wounds*.—Haemothorax. Leave alone as regards aspiration unless the patient is dyspnoeic at rest. They travel comfortably (on sulphonamides) and can be aspirated under the best circumstances at the base.

Sucking wounds. Don't sew up but stop the sucking with a sulphonamide vaseline gauze pad kept well in position with strapping or even stitches. Conservatism is the keynote in chests.

SUPPLIES AND DISTRIBUTION OF PENICILLIN

Statement by Medical Research Council

It is now generally known in the profession, and even to some extent among the laity, that penicillin has remarkable therapeutic properties, and frequent inquiries are made about its availability. The following is a statement of the present position. In order to extend and amplify the pioneer work of Prof. Fleming, and of Prof. Florey and his colleagues at Oxford, the Medical Research Council, at the request of the Ministry of Supply, last March appointed a Committee on Clinical Trials of Penicillin, which controls the distribution of penicillin for purposes of clinical research, and is instructed to employ the present limited supplies to gain new knowledge of the curative possibilities of the drug rather than merely to repeat the therapeutic successes of which it is already known to be capable. In addition to a quantity allocated to the War Office for trial in wounds in the Army over-seas, supplies of penicillin for research into the systemic treatment of selected infections have been allocated to four centres in this country; four others are receiving, or are about to receive, smaller supplies for the study of local treatment only. It has not seemed advisable at present that these centres should be issued generally known, nor that an invitation should be made to refer suitable cases to them, because the numbers of patients which can be dealt with are so limited that this could only cause widespread disappointment.

The policy of the therapeutic trials now proceeding is to treat conditions known to be susceptible only so far as is necessary to define the minimum effective dosage, the best methods of administration, and any factors not yet studied on which success may depend, and to explore the possibilities of penicillin treatment in conditions hitherto unstudied from this point of view. Penicillin is known to have an action on many species of bacteria, some of which cause a great variety of lesions: these, together with the many forms which an infected wound may take, afford a wide field of study.

Even with the fullest co-operation of the Ministry of Supply and of the manufacturing firms, the difficulties in making penicillin on a commercial scale are still so formidable that the present output in this country is scarcely sufficient for the work in the four main research centres, and is only a minute fraction of the quantity which would be required if all cases of even a few specified infections were to be afforded treatment. Production on a greatly increased scale is being urgently undertaken both here and in the United States, but in both countries the requirements of the fighting Services are likely to absorb most of the output for some time to come, and to name a date when adequate supplies will be available for general use is at present impossible. For the reasons given above it will be appreciated that requests for supplies of penicillin for the treatment of individual patients cannot, under existing conditions, be met.

F. S. Daft and co-workers (*Publ. Hlth. Rep.*, Wash., 1942, 57, 217) report the occurrence of extensive hyaline sclerosis and calcification of blood vessels in young rats given a diet containing 1% sulphaguanidine for from 62 to 192 days. The changes so far have been observed in the small arteries of the heart, lungs, kidney, pancreas, and the intestinal submucosa.

SPEECH THERAPY

Nova et Vetera

The Association of Speech Therapists, formerly the Remedial Section of the Association of Teachers of Speech and Drama, held a conference at B.M.A. House, London, during the first week of August. The organization of speech clinics and their relation to medical, educational, and social services and the allied professions were a principal subject of discussion. An entertaining demonstration of animal language, including gramophone records of such usually dumb beasts as the Bactrian camel, was given by Dr. Ludwig Koch, who has been working at the subject with Dr. Julian Huxley. There were also two lectures by medical men. In one of these Dr. Helen Watson spoke on the value of complete relaxation as a means of overcoming many nervous and other troubles, and in the other Dr. C. Worster-Drought developed the interesting subject of congenital auditory imperception and its relation to speech defects.

Auditory Imperception

Children who suffer from auditory imperception, although able to hear sound, fail to appreciate the significance of spoken words and to store their memories with words heard. On a casual observation they may appear to be deaf, and only by special tests can their cases be differentiated from ordinary types of deafness. Some of the children are mute; others have a language of their own, unintelligible to the stranger though understood by their parents. Dr. Worster-Drought emphasized the need for a careful and detailed examination of hearing before a definite conclusion is reached in a suspected case. If the condition is regarded at once as auditory imperception it may mean that real deafness in varying degrees is neglected. Tests which depend upon the subject's repeating what he hears should not be employed; these people can often repeat the sounds they hear: the trouble is that they do not understand them. Only tests which require that the subject shall understand the meaning of the sound can be accepted. Sometimes even the ability to repeat sounds is defective; the number of syllables may be caught correctly but not the actual sound. The recognition of musical sounds varies considerably in cases of this kind; some of the subjects cannot recognize discords made by themselves on the piano. The speech of the individual suffering from auditory imperception is rarely spontaneous; it is monotonous and lacks stress and intonation: often it is a series of unrelated sounds without grammatical structure. Yet, as a rule, the mental condition of these children is normal if they have been brought up in a good environment and treated with sympathetic understanding by parents and teachers; on the other hand, if neglected they may appear imbecile from deprivation. Cases are on record in which speech has not been acquired before the age of 12. Such children may find their way into schools for the deaf, and when, sooner or later, it is discovered that they can hear they are put down as lazy and inattentive.

For a long time, said Dr. Worster-Drought, this speech defect was considered to be an independent condition; its relation to the auditory mechanism was not understood. In its severe form it is rare, but minor degrees are common. It seems to appear much more often in boys than in girls, and there is a familial factor but no evidence to show how it is transmitted. The cause, whether birth trauma or some biological variation of the nature of aphasia, can only be a matter of speculation. Treatment depends on the early recognition of the defect, and the general aim must be the "socialization" of the individual and the planning of his education so as to secure for him a normal relationship with his fellows and qualify him for occupation. Training of the articulation by sound and touch and the teaching of lip-reading in the same way as with deaf-mutes may be applied, but teaching in classes for the deaf is to be avoided.

J. Singh (*Ind. med. Gaz.*, 1942, 77, 733) records a case of diphtheria of the glans penis in a boy aged 5 years, shown by an ulcer extending from the corona to the external urinary meatus. There was no lesion in the throat. Organisms morphologically resembling diphtheria bacilli were grown from the lesion. Recovery rapidly followed administration of diphtheria antitoxin.

THE BICENTENARY OF THE BIRTH OF LAVOISIER

Antoine Laurent Lavoisier was born in Paris on August 26, 1743. The son of a rich advocate, he studied anatomy in addition to chemistry and the other sciences. While still very young he joined the famous Guettard in a mineralogical tour, and at the age of 25 he entered the *Académie*. Almost at the same time he became a member of the *Ferme*, the body of private financiers who purchased the right of collecting the national taxes. Thus began a very active administrative and business career. In 1771 he married Marie Anne Pierrette Paulze, a girl of 14, who developed into a brilliant woman. A few years later Lavoisier was appointed an inspector of gunpowder for the Government, and till 1792 he and his wife resided at the Arsenal. His guidance enabled France to maintain the large stocks of powder necessary for the revolutionary wars. But Lavoisier had other interests, including politics. He did much work for the Academy, and he served on various committees dealing among other matters with agriculture and with weights and measures—the foundation of the metric system. He was in constant touch with all the brilliant men of his age. In 1791 he was appointed Secretary to the Treasury. But as a former Farmer-General he had to suffer under the suspicions—later shown to be unfounded—which fell upon the directors of the *Ferme*. An inquiry was instituted. The evidence was weighted heavily against the Farmers-General, and in November, 1793, they were arrested. After long confinement they received the farce of a trial on May 8, 1794. They were condemned to the guillotine, and the sentence was carried out forthwith. The bodies of Lavoisier and of the twenty-seven other victims were thrown into nameless graves.

Busy though he was with other matters, Lavoisier devoted six hours daily to scientific work. Although he was responsible for investigations into the purification of water, the lighting of cities, and on geological and meteorological subjects, his fame rests on his brilliant chemical synthesis. He has no claim to be regarded as the "discoverer" of oxygen. The active principle of the air had been suspected by Lower, and more especially by Mayow in 1674, but the significance of Mayow's "spiritus nitro-aereus" had long been forgotten—swamped in the subsequent development of the phlogiston theory. The gas was prepared by Scheele in 1772 and independently by Priestley in 1774. Priestley named it "dephlogisticated air," and he measured roughly its superiority to ordinary air. Priestley also recognized that it could be used to increase the force of a fire, and he suggested its use in medicine. But it was left to Lavoisier to demonstrate the vital importance of this newly recognized gas in combustion, in respiration, and in the formation of acids. The name "oxygen"—i.e., acid-producer—is due to him, and he must be credited with the first clear conception of the significance of the gas.

Mayow a century before had postulated that his "spiritus nitro-aereus" is necessary for life, and he showed that an animal in a closed vessel dies more quickly if a lighted candle is also introduced. He suspected that the vital particles of the "spiritus" unite with food particles in the muscles. This work was forgotten, and it was Lavoisier, alone and with Laplace, who established an equation between the quantity of heat formed in animal metabolism and that in ordinary combustion. He showed that animal heat results from oxidation—in the lungs, as he thought—and with Séguin he measured the oxygen consumed and the carbon dioxide and water produced in respiration. He was thus the founder of exact investigations on metabolism, and his wife's sketches show him in his laboratory using an apparatus which must have been one of the earliest attempts at quantitative calorimetry.

As a constructive thinker on chemical matters Lavoisier was very great. He virtually destroyed the phlogiston theory; he enunciated the law of indestructibility of matter, and he was largely responsible for the introduction of the chemical nomenclature which we use to-day. His *Traité Élémentaire de Chimie*, published in 1789, made chemistry a unified science. It was to chemistry what Newton's *Principia* was to the physical

sciences. On the day after Lavoisier's death Lagrange said: "*Il ne leur a fallu qu'un moment pour faire tomber cette tête, et cent années peut-être ne suffiront pour en reproduire une semblable.*"

E. A. UNDERWOOD.

RUSSIAN SURGEONS AND RUSSIAN SURGERY

BY

R. WATSON-JONES, F.R.C.S.

Mr. Watson-Jones was one of a group of British surgeons who recently visited the U.S.S.R. under the auspices of the Medical Research Council and the British Council, and has contributed the following article at our request.—Ed., B.M.J.

It is not easy to form an immediate impression of the people of Moscow because the closing of all shops except the few which supply food, the lack of colour, lighting, decorating, and flowers, the striking disappearance of dogs, cats, and pets, so that I saw but one dog in three weeks, the wearing of shoddy clothes and footwear so that the Army might be well clad, and the limitation of amusement to an occasional seat at the ballet are the restrictions of war, and they emphasize unduly the solid, determined, plodding, almost expressionless features of men and women in the streets. Life in Russia has been hard; pleasures have been few. It is true that there is no sign of malnutrition; the rations of the worker are comparable with those in England; I searched for evidence of rickets and found none; the children are bright-eyed, healthy, and happy. But there have been privations, and the faces of the people show it; it is not always easy to know what they are thinking. Nevertheless one impression was quickly formed by the surgeons who represented England, Canada, and the United States in a recent visit to the Soviet Union. It was impossible to mistake the spirit of overwhelming hospitality with which we were received. It was impossible to misjudge the very cordial friendship which developed. From high officials of the Commissariat who received us at the airfield, to hotel staff members who apologized because they could offer no more than one hot bath a week; from generals who thought of our comfort during arduous journeys over shelled roads and demolished bridges, to soldiers from Stalingrad who insisted on our climbing and entering the mightiest tanks; from hospital superintendents and commanding officers whose invitation to a cup of tea implied a heavily laden table and a two-hour banquet, to attendants in the Park of Rest and Culture who were satisfied only when we shared the terrors of a dummy aircraft which simultaneously rolled and looped; from crowds at the Exhibition of Captured War Material whose smiling comments included the words "Angleeskee" and "Americanskee," to the handful of determined survivors remaining from the half-million inhabitants of demolished Vyasma; from all people and all professions we received the greatest kindness and the most convincing evidence of friendship and good will.

We formed a second, very vivid impression on seeing the astonishing capacity of Russian women for hard work. Men employed in repairing roads and relaying tram tracks worked with an intensity which reminded us of home; but the women who shared their strenuous task paused less often and were more consistent. Girls of 18 and 19 drive the trams and scramble on to the roofs to repair the trolley arm. Traffic is controlled by sturdy women police armed with a black-and-white striped truncheon and a pistol at the hip. Hundreds of miles of military roads are guarded by women soldiers with Tommy guns. Women doctors, women surgeons, and nurses work in the front line; many of them wear the chevrons of multiple wounds. The Inspector-General of Medical Services of the Red Army is a woman.

Front-line Hospitals

Not only do nurses attend the wounded, but in the intervals of battle they build the hospitals. One of the front-line hospitals we visited is built in territory which until last March was occupied by the enemy; within four months a 2,000-bed hospital has been almost completed by nurses who are obviously

skilled in the use of the saw, the plane, and the spirit level. Many of these hospitals are buried six feet deep and covered with a thin layer of soil and turf. They are constructed wholly of wood from the forests in which they are perfectly camouflaged. Trees standing within an inch or two of the walls are left undisturbed, and wards may even be built round living trees which grow out of the roof, only branches within the building being stripped.

The reception-sorting ward is completely free of all fixtures and equipped only with collapsible trestles on which stretchers are laid. Washing and shaving is recognized as an important first-aid measure, and part of the ward is devoted to baths, or rather to positions near the wall where hot water is sprayed over the wounded man as he lies on the stretcher. After the patient has been examined he is marked with a coloured label—red for urgent surgery, blue for redressing, white for evacuation, each numbered 1, 2, or 3 in accordance with priority, and sent to one of the special wards—orthopaedic, neurosurgical, thoraco-abdominal, lightly wounded, etc. Each ward is equipped with its own x-ray, wound-dressing, and operating suite, and treatment by skilled specialists is instituted within 10 or 20 miles of the front line and within 24 to 48 hours of wounding. The provision of every ward with theatre and x-ray equipment may seem wasteful and extravagant; but it is to be recognized that each is a 200-bed ward, the equivalent of a small hospital which empties and refills every third or fourth day as patients are evacuated to the rear, and such a flow of casualties is more than enough to saturate one set of theatre and x-ray equipment. This concentration of 200 wounded to a single ward is possible because patients are nursed on stretchers in tiers of two or even three, laid on rods which are suspended from the upright supporting posts of the roof. The rods are easily turned back so that in periods of less intense activity only the middle bunks, or the middle and lower bunks, need be used, and sometimes the whole space may be cleared.

Such emergency hospital construction, with its emphasis on x-ray, plaster room, and operating theatre facilities rather than on ward design, was most impressive, particularly having regard to the speed of building which it permits, the conservation of space, the adaptability to a varying flow of casualties, the economy of transport of patients before and after operation, and the segregation and specialization which are possible almost at the line of battle. The principle of segregation is carried beyond the specialist wards of sorting-evacuating hospitals to specialist hospitals further behind the line of two to four thousand beds each. So great has been the flow of casualties that it has even been practicable to devote 2,000-bed hospitals to gunshot fractures of the thigh, to penetrating wounds of the hip-joint, and to other special injuries.

Closed-plaster Technique

The closed-plaster technique is used for all major wounds, compound fractures, and joint injuries. Prof. Yudin claims that in the surgery of war this was first practised over ninety years ago by the famous Russian surgeon Pirogof.

"After the resection had been made, instead of amputation the limbs are put in plaster-of-Paris casts . . . but the main thing is that not all surgeons know how to apply a good plaster cast, the closed one . . . that is why I justified myself for applying closed and windowed plasters to every field knee wound. . . . I was surprised with the unacquaintance of the Italian and French surgeons with my method during the war of 1859. Neither the Frenchmen nor the Italians tried to apply the plaster. The worse it is for them."

Yudin teaches that after wound excision no tube or drain should be used, and no gauze pack or other "foreign body" should be inserted; an unpadded plaster cast is applied directly over the wound. I was interested to learn of this departure from the practice to which we are accustomed in this country, because I have always been impatient of discussion on the relative merits of vaseline gauze, plain gauze, and other forms of "pack." It is clear that in comparison with the principles of wound excision, immobilization, and freedom from repeated dressing, these are unimportant details of individual technique. But there is one essential difference of principle in the methods which are practised in Russia. "A large excision of all injured and all contused tissues" is recommended no matter how many

hours or days have elapsed since wounding and "independently of the presence and degree of infection." In England we believe that free excision is indicated only during the first 12 or possibly 24 hours, and that after that time wide dissection is liable to disseminate infection; we think that the correct treatment in late cases is incision and drainage rather than excision and drainage. When I submitted this contrary view Yudin maintained with all the dynamic force of which he is capable that no matter how acute and widespread the infection "simple incision and tamponade with gauze, or any kind of antiseptic, or vaseline by Winnett Orr, cannot replace the necessary excision of all damaged tissues and, still more important, the removal of foreign bodies. Such incisions are not a surgical aid, but only a primitive temporary measure in the most hopeless circumstances owing to enormous quantity of work. Such patients should be regarded as having undergone no surgical treatment at all."

Personally I am still unconvinced, but it is clear that further study is necessary. Large series of cases, comparable with Yudin's, with a similar proportion of late, "malignant septic," and desperately ill patients, must be examined. The mortality must be compared with Yudin's figures (3 to 30 days 4.1%; after 30 days 1.3%). The amputation rate must also be compared (6.5% immediate amputations for vascular damage and gangrene, and 5.5% late amputations for general septic condition).

Joint Wounds

A similar principle is adopted by many surgeons in the treatment of joint wounds; resection of the joint is preferred to arthrotomy in both early and late cases. In the hip-joint the head and neck of the femur is removed; in the knee-joint the resected bone varies from a thin sliver to a large section of the femoral condyles, but always including the joint capsule, without which drainage is considered inadequate. Sulphonamides are used and the limb is immobilized in plaster. On this subject there is some divergence of opinion, and arthrotomy of acutely infected joints has been advocated more recently in preference to resection. This coincides with our view. One of the striking features of the surgery of this war has been the excellence of function and the free mobility which are so often regained after the treatment of penetrating joint injuries by early excision of the wound (but not resection of the joint) and immobilization in plaster; we believe that resection at the height of acute infection is dangerous; and we think that excision of the head and neck of the femur leaves an unstable joint which is far less perfect in its function than a firmly ankylosed one.

Cerebral Surgery

Surgeons in this country are already familiar with Burdenko's pioneer work in neurosurgery, with Proper Graschenko's clinical investigation into gas-gangrene infection of the brain, and with Lena Stern's physiological research on the blood-brain barrier and intracisternal injection. The main principles adopted in the treatment of cranio-cerebral wounds are: (1) serious cases are not to be operated upon until shock is controlled; (2) operation is to be deferred until skilled surgeons and equipment are available; expert investigation and operation two or three days after wounding is better than inexperienced operations performed immediately; (3) haemorrhage and a rise of intracranial pressure are the only indications for operation on the spot; (4) the longest safe period of deferment is three days; after that time the operative mortality rises steeply; (5) specialized hospitals with neurosurgeon, neurologist, neuropathologist, ophthalmologist, oto-rhinologist, and radiologist must therefore be available within three days' travel of the battle line, and patients should usually travel by air at heights not greater than 5,000 metres; (6) patients with cranio-cerebral wounds stand evacuation better before than after operation; when operation has been performed the wounded man must stay where he is for fifteen to twenty days; (7) in the diagnosis and location of cerebral abscess contrast media are used, and excision with removal of the capsule is considered the treatment of choice.

Blood Transfusion

The blood-donor system of Moscow is worthy of emulation throughout the world. In one hospital we saw 300 donors bled in a single day; in another there were no fewer than 600.

Many thousand pints of plasma are also collected from filial institutes in other cities. Donors are assembled in different rooms in accordance with their blood groups, which have already been tested. They are given a special fat-free meal, undressed and clad in sterile theatre clothing, including caps, masks, and cloth boots. For each blood group there is a separate operating theatre. A single woman surgeon with two nursing sisters and five technical assistants controls six operating tables simultaneously. The work is done with skill and precision. It is a model of careful organization, of the highest possible standard of theatre asepsis, and of repeated check and control of both contamination and accurate blood grouping. Dried plasma is put up in small ampoules, connected by means of a rubber tube and clip to a larger ampoule of sterile distilled water, ready for immediate mixing and administration to the patient. Blood is flown to the front in thermostatic boxes, lined with glass wool and cork, with a central compartment for ice or warm water according to the season. At the regimental aid posts and field mobile hospitals the blood is stored in deep pits; the temperature is tested thrice daily, and in the summer months it is controlled by ice blocks which were stored underground after cutting in winter.

Other Fields of Surgery

So many aspects of surgery were studied that selection is difficult. One might write of ultrasonic emulsification of therapeutic agents, of intracarotid injection of sulphonamides, of intracisternal injection of antitetanic serum, of cap splints for maxillary fractures, of gap fractures of long bones, of acrylic resin for dentures (which are delivered many miles behind enemy lines), of plastic reconstruction of the penis by tube grafts and cartilage inlays producing an organ capable of both urination and erection, of the treatment of oesophageal stricture by jejunal transplants, or of the excellent system of medical education by which 25,000 doctors a year are trained. The astonishing fact is that so high a standard of surgery has been achieved in a country where the full development is so young and where contacts with the surgery of other countries has been so limited.

We believe that Soviet surgeons would gain from visits to other countries; we believe that in this way their technique would be improved; but we believe with equal conviction that we gained from our visit to them. We did not approve of all we saw; we disagreed on the treatment of frost-bite; we were unconvinced of the merit of muds, balsams, and wood distillates; we thought that our rehabilitation was better than theirs. But on the other hand much of their work is better than ours: their specialization is excellent; their training of medical students is more thorough; their organization of surgical services is superb. Each of us can learn from the other. In the words of Academician Burdenko: "Our friendship must be much tighter."

RELIEF OF DISTRESS IN THE PROFESSIONS

The Professional Classes Aid Council was a creation of the last war. Soon after that war began it was appreciated how hardly hit were men and women in the professions—in some professions more than others—for whose work the demand had suddenly collapsed. But, as may easily happen again, post-war conditions impoverished many people of the professional classes to an even greater extent than those of war itself, and the Council was reconstituted in 1921 and has carried on its excellent work until the present day. It is a very representative body, its council of over eighty members comprising representatives of nearly all professional bodies with a benevolent side to their activities. The British Medical Association is represented by Dr. Henry Robinson. Last year the Council spent £12,417 on relief, but for the third year in succession there is a debit balance—this time of £1,710. A feature of the work of the Council is the education of children whose parents have suffered misfortune—in some cases children whose parents have been interned in enemy-occupied countries. The number of children assisted last year was 124, and the grants cover school fees, outfits, and maintenance. A very useful almoner work is being sympathetically done; while immediate pecuniary help is given where necessary, the main purpose is to set professional men and women on their feet again and to see them through their difficulties. The class of people it sets out to help are those most liable to be overlooked by ordinary charity, as many or most of them are diffident about calling attention to their plight. The address is 20, Campden Hill Square, W.3.

Correspondence

Foundations of a Comprehensive Health Service

SIR,—I was interested in the letter of Dr. H. C. Killingback (*Supplement*, Aug. 14, p. 24). The need for a considerable accession to the medical profession for the running of a comprehensive medical service is, I think, nowhere in doubt, although there may be different opinions as to its magnitude. In a paper I submitted to the Medical Planning Commission I set out the facts and figures which enabled me to come to the conclusion that the general practitioner service of a comprehensive health service could be begun on the basis that every general practitioner working a whole-time scheme could cope with 2,000 persons, and would carry out all the work now undertaken by general practitioners and the non-hospital medical staffs of local authorities. Such work could be accomplished on the basis of a 40-hour week with, in addition, the time involved in such night duties as might arise in connexion with the care of 2,000 persons. Four weeks' holiday per annum was also allotted to each practitioner in such a service.

It was, however, indicated that this was only a beginning, and that if the work were to be extended to include such services as suggested in para. 4 of Dr. Killingback's letter, the number of persons on a doctor's list would have to be reduced below 2,000. As the population of Great Britain in 1938 was some 46,000,000 and as general practitioners and local authority doctors are computed by Dr. Killingback to number 25,000, it will be seen that there is in any case a sufficient number of general practitioners to make a beginning.

I am unaware that any responsible body advocates the immediate adoption of a whole-time salaried service. The Society of Medical Officers of Health does, in fact, support the policy of a whole-time salaried service, but they do not suggest its immediate adoption. They realize that a comprehensive health service, whether on the basis of whole-time or part-time service, requires to be established on a sound foundation, and that there must be something in the nature of a transition period during which foundations may be laid and various methods of medical service tried out. In the report of the society dated Nov. 20, 1942, they clearly indicated the spade work which was necessary in order that a comprehensive health service might ultimately be established. The order in which this work should be carried out was this:

1. That the Government put its own house in order in the first place so that a Health Ministry be established to include all the health functions of Government Departments and with health as its sole function. This could be done quickly and during the war.
 2. That local government areas of sufficient size and with adequate resources be established, in each of which the administration of a comprehensive health service could be satisfactorily carried out. This, again, could be done by the Government without undue delay and without unduly impeding the war effort.
 3. That following upon 1 and 2 powers should be given to the new local government authorities to plan and develop such a comprehensive health service as might be considered best for their respective areas after consultation with the local medical profession.
- In coming to this conclusion the society, while supporting a whole-time salaried service, nevertheless realized that all reasonable methods of medical practice should be tried out before any final conclusion was reached. Such experimentation will take time, and would be almost impossible to conduct it during the war.

In the course of the discussions of the Medical Planning Commission and Representative Committee and other bodies nothing has appalled me more than the idea, often expressed, that a comprehensive health service must be established at once and that time was "of the essence of the contract." After all, even in these strenuous days of war, the public does receive medical attention, if not so promptly as before, and we are told on the highest authority that the national health was never better. Why, then, all this hurry? In any case immediate steps towards a comprehensive health service can be taken if the Government will play its part and proceed to lay the foundations by establishing a real Ministry of Health and suitable areas for local government. Following upon these necessary preliminary steps the medical profession can

be relied upon faithfully to perform its task of working with all concerned so that the public may have the best health and medical services within its power to give.—I am, etc.,

Willesden.

GEORGE F. BUCHAN,
Medical Officer of Health.

A Prisoner of War on State Medical Service

SIR,—After nearly 3 years of total isolation from British medical literature in this little outpost contact has been re-established. Several copies of the *Journal* have lately trickled through. We were in touch with Continental progress through subscription to a local medical journal, but events at home depended on private correspondents. From these we hear rumours of a projected State Medical Service, almost unbelievable since our informants seemed to think it already *fait accompli*. How justified was our scepticism! Surely it was easier to obtain agreement among mediaeval theologians than among modern doctors. The B.M.A. seems anxious to have the opinions of as many doctors as possible. We think that the only way to get a State service in our time would be to ask the opinions of as few as possible, and preferably only one to ensure unanimity. In either case the number of malcontents would be the same.

And why cling to the "free choice of doctor" myth? All our patients for 3 years have had no choice at all, and although we have treated patients of five nationalities—a feat involving no small linguistic difficulty (lay interpreters are a menace)—the results have been no worse than at home, and the number of dissatisfied patients negligible. We hasten to add that the expression of dissatisfaction by the patient entails no material disadvantage to him here. Anyway, how often does the hospital patient choose his house officer or his "honorary"? Meanwhile we follow with interest and good will your efforts and wish you success "in our time."—I am, etc.,

Stalag VB, Germany.

STANLEY GILDER,
Capt., R.A.M.C.

General Principles for Future Medical Services

SIR,—To anyone who has at heart the desire to see the profession retain its freedom and respect as an independent body the principles which the Council of the B.M.A. has adopted must come as a bitter disappointment. In nearly every other word there is the assumption that our battle for freedom has already been lost—if, indeed, it has been fought—and that the peace-term negotiations will only determine which body is to take over control of us.

Although the principles do not at present admit of our being converted into a salaried branch of central or local government service, they clearly lay down that future changes must be preceded by the setting up of a "central administrative structure by the State for the central administration of the medical services in the future." This means control by the State direct or control by the State via an intermediary body such as the B.M.A. The continuation of the personal relationship between patient and doctor and right of choice is only the sugar coating to the pill which is coming to the profession in the shape of loss of freedom and control by central authority. Although we may not negotiate away our complete independence now, we shall part with three-quarters of it and so prejudice heavily the position of the next medical generation. Our sons, born into partial captivity, will be an easy prey to a future Ministry of Health, who will complete the second stage of the operation, and, with the loudest protestations of good faith, secure final and absolute control over what was once a respected profession.

If anyone has doubt about the control which is now in sight let him reread the principles adopted by the Council of the B.M.A., paying particular attention to Recommendations A4, D (first part), E (first part), F, I, K, and L, and Immediate Proposal I. In the whole lamentable document there is not a hint that the Representative Committee wants to put up a fight to retain our status as an independent, learned, and liberal body. The discussions have been conducted in the greatest secrecy, and even now they are completed no word may be hinted at by our Representatives until the White Paper has been published. It follows that from this the Government will benefit, not us.

In the future Division meetings members will have the opportunity either to express their views and insist on freedom

or to give the negotiating body permission to hand over our independence and place us under central control. Let us make up our minds that there will be no more voting on prepared resolutions based on what the Representative Body *believes* to be the opinion of the profession. Let there be more statement of fact about our opinions, and due consideration given to the fact that even yet it is not too late for the R.B. to take a firm line with the Ministry. Our freedom can be preserved at any rate until the doctors in the Services come home and have the opportunity of assisting in the reconstitution of the medical services, if they then think that it is necessary.

Above all, it is necessary for every doctor to do his duty by asking himself three questions before voting for a scheme which will lead to central control: (1) Is it going to do the public any good? (2) Is he allowing himself to be used as a pawn in a game of political chess? (3) Is he voting away a birthright of the next medical generation? At the same time let him bear in mind that half the world is locked in a bloody struggle for freedom and the right to live an independent existence. Also, his many colleagues on active service who are engaged in this struggle will feel little gratitude to him for voting away their freedom in exchange for a system of central control, the key positions in which will have been earmarked for highly paid officials promoted in their absence.—I am, etc.,

St. Ives.

E. C. ATKINSON.

National Health Policy

SIR,—The B.M.A. rightly states that the provision of adequate food, good housing, good working conditions, ample recreational facilities, and a widespread health education are more important for the health of the nation than a "reshuffling" of the medical services. The B.M.A. then proceeds to argue that the Government should first provide all the social and environmental conditions for good health, and only, after this would have the right to interfere in the organization of the medical services. This argument is, in reality, extremely hollow, apart from being ill-becoming to our profession, for who will listen to us if we refuse to put our own house in order?

It is a complete figment of the imagination to think that any democratic Government can carry out important social and economic reforms without the active encouragement and support of the people, organized in political parties, trade unions, professional associations, etc., and without having to sustain a severe struggle against powerful interests which oppose those reforms. Shall not the medical profession lend the maximum support to the forces fighting for the achievement of those environmental conditions which make for better health? It is not enough that leaders of the profession and public figures as Prof. Ryle, Lord Horder, or Sir Farquhar Buzzard should intermittently write letters to the Press, give lectures, or speak in Parliament about health matters and the importance of social medicine. The task is so big that it requires the joint efforts of the whole profession, and requires also that we should educate ourselves. This can be done only if there is continuous free interplay between the preventive and curative services, and between the medical and the other allied health services—that is to say, we need a national health service based on the health-centres and the hospitals at the earliest possible moment. It would indeed be a melancholy and defeatist policy to wait for the advent of a new generation of medical practitioners educated by the medical schools in social medicine. This new generation of practitioners would also find that the conditions of practice from isolated private surgeries would frustrate and stultify all their aspirations and knowledge.

The B.M.A. and Dr. Geoffrey Bourne wish to enlarge the already regrettable gap between scientists and politicians. We should, instead, work to bridge that gap, so as to bring the voice of science nearer to the people and in the counsel of their political leaders. If we ally ourselves to the democratic forces in the nation we need have little fear that we shall not be able to maintain, in an organized health service, our democratic traditions, scientific freedom, and a decent standard of living. Proof that this statement is not based on pious aspirations only is given by the recent introduction by the

L.C.C., which controls the largest group of hospitals in the world, of enlightened measures that will meet the most important criticisms the profession justly raised against the hospital services of local authorities. The world is moving on, and with it local authorities.

The reorganization of the medical and allied health services thus forms an integral part of the larger aspect of a national health policy, which, of course, must include adequate housing, nutrition, recreation, and education.—We are, etc.,

Queen Mary's Hospital, Sidcup.

C. K. VARTAN.
E. MONTUSCHI.

Fact and Fancy in Poliomyelitis

SIR.—I would like to congratulate you upon the masterly leading article in the *Journal* of July 31. There is little to add to your critical review of the Kenny "concept." Nevertheless I would like to remark upon the view of the Kenny enthusiasts that there is something strikingly new in Miss Kenny's methods of treatment by meticulous nursing care, freedom from splints, and hot packs. You have rightly stressed the weight of authoritative opinion in the United States upon the question of infantile paralysis, which has contributed so importantly to our knowledge. In that regard, I would like to draw attention to a classical paper on poliomyelitis written by Peabody, Draper, and Dochez in 1912 (Monograph No. 4, Rockefeller Institute, New York, 1912). May I quote from their section on treatment:

"During the acute stage absolute rest in bed is, of course, a necessity." "The most prominent indication for treatment is usually pain . . . this necessitates the utmost gentleness and care in moving or turning the child." The psychological approach is emphasized. The weight of bed-clothes must be removed. In some cases "a light well-padded splint seems to steady the limb." "In general the most effective simple agent for overcoming pain seems to be heat. Wrapping the limb in cotton-wool, blankets, hot packs, and hot-water bottles gives great comfort." "When the acute symptoms pass, more active treatment directed towards the prevention of deformities and the restoration of muscular function should be instituted." "As soon after the first fortnight as the child can bear any movement or handling without pain, massage should be begun." "Contractures begin to develop early in poliomyelitis, and it is essential that they should be guarded against from the onset."

Apart from cradles, "sandbags may be used to support a limb"; or "light apparatus, well padded" and "loosely applied so that there is no obstruction to the circulation." "The danger of apparatus is that it will keep the limb too quiet and prevent any attempt to use weakened muscles at precisely the period in which both active and passive motions are most to be encouraged. To obviate this it has been our custom to have the apparatus applied at night only, and to leave the limbs free to move during the daytime." "We have begun massage as soon as pain would allow and given it twice daily. Its chief usefulness probably consists in assisting the circulation by replacing the effect of lost muscular activity." "Heat similarly exerts a good influence on the circulation. With massage passive motion is used, the rhythmic performance of certain movements stimulating the patient to try to attempt them himself. Of all the methods, however, by far the most valuable one is active movement, or training." The psychological ingenuity required to achieve this is discussed in brief. (The italics in the above quotations are mine.)

Those of Miss Kenny's medical associates who wish to enunciate a new concept of the pathology in muscle should read another excellent article from the United States—namely, that dealing with the changes in denervated muscle by Dr. Sarah S. Tower (*Physiol. Rev.*, 1939, 19, 1).—I am, etc.,

Exeter.

NORMAN CAPENER.

Ariboflavinosis Syndrome

SIR.—I read your leader on the ariboflavinosis syndrome (July 24, p. 110) with more than passing interest, for I have done a good deal of research into the tropical syndrome of retrobulbar neuritis with sore tongue, mouth, scrotum, etc., and was the first to describe a retrobulbar neuritis. (You refer to Métiévier as "she." May I correct you? Métiévier is a man. I knew him well as a fellow-student at Bart's, and also we have exchanged reprints.)

Your article is obviously well timed and necessary. As one interested in tropical deficiency states one has noticed too ready

an acceptance of a new biochemically discovered factor being used therapeutically, and too sweeping claims made for its success in dealing with a syndrome. My own experience in this syndrome up to 1938 (it included nicotinic acid, and mine was actually the first report to show the relative failure of its therapeutic use in this condition: see *J. trop. Med. Hyg.*, April 15, 1939) was that it was very simple to demonstrate that marmite cured the frankly visible signs on mouth, scrotum, etc., but it was a much longer task to include the whole curative effect on the eyes as well. It took some six months' closest observation, as against almost days in the other case. An end-result to include the whole syndrome was only possible over a comparatively long period. With riboflavin therapy some reports appear to be too early and lacked completeness. It is clear that such reports have indeed gone for the more visible signs only, and, therefore, part of the syndrome, not the whole. Again, there is much conflicting evidence as to exactly how much the tongue and scrotum do respond to riboflavin, and this is where I feel your article is so timely.

My particular reason for so welcoming your article is the danger, especially in the Tropics, of claiming an all-too-simple solution or explanation, and with that an apparent simple solution of the important food problems at issue. For the syndrome is not only excessively common but may be very severe. It seems there must be more than one factor involved, and a lot of misunderstanding can be created by over-simplifying the cause, particularly if the whole weight of proof is manifestly lacking.

I feel that a great deal of interest attaches to the possible part that poor-grade high-excess carbohydrate diet may play in production. This is not an original claim, but as early as 1930 I drew attention to "gari," a processed manioc derivative, in its constant place in the dietary in affected people in Nigeria. More recent information has given me cause to think that rice is equally likely to play such a part in other countries where it is a staple, and I have published some of my reasons (*J. trop. Med. Hyg.*, Sept. 1, 1942) to that effect. In that article I did not care to say—for reasons which might raise controversial feelings—that, with the exception of Stannus, nearly all the better known and accepted authorities on research had up till 1936, or later, claimed that this sore-tongue syndrome was due to vitamin A deficiency. So persistent and compelling was that influence that the League of Nations Report on Nutrition (1937) insisted this was so. The effect was a wholesale deviation to fat preventive foodstuffs in the rice-eating countries. And yet this syndrome is common to almost every rice-eating country: Malaya, India, Ceylon, China, West Indies, Sierra Leone. It is equally noticeable, again, that visual symptoms are now being found there which seemed to be completely overlooked before Sydenstricker's work. I see no reason why rice should merely hold the field for one particular vitamin B deficiency disease—namely, beriberi—and have no part in the production of other B-deficiency states. Food planning for the future will be of little value if it includes in poor areas a wholesale increase of rice or other staple foods poor in B vitamins.

I should like to end my letter by saying how deeply impressed I have always been with Stannus's work; how little recognized it has been. I think it was in 1940 that he advanced an interesting theory of the possible biochemical causes of pellagra, and *inter alia* he produced the idea that sugars and starches in excess could so disturb metabolism. It seems that there is much back this view, especially where there are no compensating factors in the rest of the diet, or rather insufficient compensating factors.—I am, etc.,

Blackpool.

D. FITZGERALD MOORE.

Specific Gravity of Cerebrospinal Fluid

SIR.—All those who are interested in spinal anaesthesia will, I am sure, feel grateful to Mr. W. Etherington-Wilson (Aug. 7, p. 165) for having investigated the specific gravity of normal cerebrospinal fluid with such admirable thoroughness. There is no doubt that many of the statements which appear in some of the most reputable writings on the subject have been copied from book to book with no attempt to confirm them by personal observation. This criticism, however, cannot be

directed to an article ("Precision in Spinal Anaesthesia," *Lancet*, July 30, 1938) in which I ventured to offer a friendly criticism of the Wilson method on the basis of the variability of specific gravity of the cerebrospinal fluid, although acknowledging that in practice the method had proved its worth.

The variations which I then mentioned—from 1.004 to 1.01—were observed in a very careful, although small, series of investigations which were undertaken, in conjunction with late Dr. Howard Jones, as far back as 1930. The expert who estimated the specific gravity for us used the most accurate method possible—namely, he used the specific gravity bottle. He informed us that the bead method was inaccurate when applied to fluids of this description, so that, although weighing method required not less than 10 c.cm. of fluid, we were able to find a small series of cases in which the withdrawal of this quantity of fluid as a preliminary to anaesthesia was thought to have no ill effect. The temperatures were, of course, carefully recorded and taken into account before arriving at the final results.

Recent inquiries among physicist friends have confirmed the inaccuracy of the bead method, for reasons which need not be entered into here. I must confess to being rather surprised that our estimations should give such variable results, since the chemical composition of normal cerebrospinal fluid is known to be remarkably constant. However, there was getting away from the observations. And so, despite the excellence of Mr. Etherington-Wilson's work, I feel that the problem cannot be regarded as finally solved.

Fluids injected into the spinal theca are subjected to a complexity of physical forces that it is unwise to rely upon theoretical reasoning in deducing what will happen, and so both the Wilson method and the one which I here describe have now been administered successfully in some thousands of cases; they must both be regarded as reasonably satisfactory. In both emphasis is laid on gravitational control, but we should not overlook the displacement factor, which probably determines the extent and in some degree the duration of anaesthesia, while the gravitational factor controls the precise localization of the anaesthetic zone.—I am, etc.,

London, W.I.

NORMAN C. LAKE

Globin Insulin

SIR.—There are two points I must mention in reply to Dr. J. Trevan's letter (Aug. 14, p. 212).

1. The following are the figures sent me by Wellcome Laboratories of a comparison (May, 1942) between globin-zinc insulin and protamine-zinc-insulin, expressed in the same way as the later results on p. 212:

Hours after Injection:	2	4	6	8	10	12
Blood sugar:						
G.Z.I.	50	66	79	81	87	90
P.Z.I.	54	63	72	77	89.5	82

This shows identical action, and I wonder why the results on p. 212 are different and which are right. I must also excuse myself for wondering if the small blood-sugar differences, p. 212 (at most 12 mg.) show a difference of practical significance in the action of these two insulins.

2. Dr. Trevan is not right in thinking my patient's reaction to soluble insulin abnormal or unusual. It is the exception and not the rule, to find any marked fall in the high fast blood sugar within 2 hours of soluble insulin in severe diabetes and the maximum fall after 30 to 40 units is between 8 and 12 hours (see *Diabetic Life*, p. 224), though this is usually obscured in routine treatment by the carbohydrate given at lunch.—I am, etc.,

London, W.I.

R. D. LAWRENCE

Mastoiditis and D. and V. in Infants

SIR.—May I express my agreement with Dr. P. W. Leath (Aug. 7, p. 168) that diarrhoea and vomiting of infants may be attributed to over-activity of the parasympathetic nervous system in relation to the gastro-intestinal tract. This, however,

not necessarily due to seventh and ninth nerve stimulation in mastoiditis. The hypersecretion and hypermotility of the t which give the diarrhoea of infants may arise in the bowel elf from products of protein decomposition stimulating the gal branches concerned to abnormal reflex activity. Furthermore, we may attribute the mortality of such cases to a spread this nervous disorder where there is no evidence of broncho-pneumonia or other localized inflammation sufficient to cause ath.

I submit that the majority of deaths associated with infantile arthra and vomiting are due to a condition of shock, in rich an overwhelming predominance of cholinergic nervous tivity produces the typical pallor, cold clammy skin, rapid ak pulse, shallow respiration, and moribund state. The eed with which this condition of shock may develop, in some ses even before there is sufficient diarrhoea and vomiting to use an appreciable loss of fluid from the body, suggests that e infection produces death mainly by affecting the central rous system and thereby the gastro-intestinal and circulatory stems.

From this point of view, the haemoconcentration typical of fantile diarrhoea and vomiting at its worst is due to the creased capillary permeability of shock, as well as to the tual loss of fluid from the body. The oedema of various rgans so often found post mortem in fatal cases of diarrhoea nd vomiting supports this view. Apparently the relatively nstable equilibrium of an infant's bodily processes is especilly susceptible to shock-producing agents whatever their ture and wherever they act.—I am, etc.,

Cambridge.

R. L. WORRALL.

SIR.—Mr. P. W. Leathart's paper on mastoiditis being a ossible cause of fatal diarrhoea and vomiting in infancy ug. 7, p. 168) restates a problem of considerable importance. s he remarks, the post-mortem finding of bilateral purulent mastoiditis in such cases is common and is well known to aediatricians. The possibility of such infection being gravita-onal is supported by the simple experiment of placing owered charcoal in the nares of infants moribund from ehydration following diarrhoea and vomiting and the recovery f charcoal from the middle ear at necropsy. Mr. Leathart's ypothesis would have been considerably stronger had he roduced statistical proof of mastoiditis prior to or soon after ne onset of diarrhoea and vomiting, and it is to be hoped e will at some future date produce such evidence. In our resent state of ignorance the statement that more often than ot no causal organism is discovered is of no value (cf. ulcerative colitis; which has not yet been associated with any causal rganism).

Mr. Leathart's condemnation of feeding infants in sickness nd health in the supine position should find universal support rom paediatricians. The question he raises is of such importance in infantile mortality that it might well engage the mmediate attention of the M.R.C.—I am, etc.,

London, W.1.

BRUCE WILLIAMSON.

SIR.—I was interested in Mr. P. W. Leathart's article on iarrhoea and vomiting in infants (Aug. 7, p. 168), and should ke to add my observations.

In a series of 63 cases of infants suffering from so-called gastro-enteritis in a large L.C.C. hospital during 1936 there ere 12 deaths. Post-mortem examinations were carried out in 8 of these, and in every case a petrositis was present; the nastoids were not always involved. In one other fatal case a double mastoid operation had been performed and pus was present; Vomiting was not a prominent feature in this series, and the degree of dehydration was very variable. The ears ere examined in all cases, but generally no abnormality was detected and the usual physical signs of otitis media vere absent.

This frequent association of otitis media and gastro-enteritis is now well recognized in L.C.C. fever hospitals, where the ear, nose, and throat surgeon is being increasingly consulted.—I am, etc.,

London, W.5.

EMILY L. SIMON.

The Government's Milk Policy

SIR.—While generally welcoming the Government's milk policy outlined in the recent White Paper, I was, like the writer of your leader (Aug. 7, p. 173), disappointed with certain proposals, and particularly with those concerning accredited milk. What possible justification is there for excluding accredited milk from a compulsory heat treatment Order? Accredited milk may perhaps be "cleaner" than ordinary milk, but is it any safer? I would submit that accredited milk is almost as likely to contain tubercle bacilli as ordinary milk, and therefore like all such potentially dangerous milk should be subjected to adequate heat treatment before consumption. It would be a real advantage and not asking too much if all milk had to conform to the present accredited standard before pasteurization. The newly introduced resazurin test sets a very low standard.

I was also concerned with the proposal to give equal recognition to all forms of heat treatment provided that the treated milk complies with the phosphatase test and a prescribed methylene-blue test. Incidentally, it is to be hoped that the latter will be of a considerably higher standard than the present bacterial count test for pasteurized milk. But surely the process of pasteurization, which has been proved beyond reasonable doubt to make milk safe without altering its nutritional qualities, should be preferred to sterilization or any other form of heat treatment. Milk, which is such an important article of diet, should first be safe to drink, and, secondly, should be as nutritious as possible. Pasteurization will achieve these two aims, but sterilization will satisfy only the first requirement. Why, therefore, give equal encouragement to both processes?

I realize that for some time there will be an acute shortage of dairy plant, and that the immediate concern is to make all milk safe, and therefore there is some justification for including sterilization of milk in a short-term policy. But I would strongly suggest that a time limit of, say, three or five years should be included in the heat treatment Order to the effect that at the end of this period the process of pasteurization would be the only method of heat treatment recognized. If this suggestion could be included, then the welcome expansion in the heat treatment of milk will be directed towards pasteurization rather than sterilization. If the proposals are left as they are, then I feel that the opposite may be the case, as there is a real danger that sterilized milk, because of its better keeping qualities, may become more popular than pasteurized milk. Such a position has already been reached in this city, where more than half of the heat-treated milk is sterilized.—I am, etc.,

J. F. WARIN.
Senior Asst. M.O.H.

Birmingham.

SIR.—May I refer to the final paragraph of your leader (Aug. 7, p. 173). The farmers do not dictate the health policy of the country. This is in the hands of the Government, who can give the public the enlightening facts if it wishes, but it dare not until it is prepared to effect the necessary remedies. It is quite unfair to pit the farmers against the community, endeavouring to place on them an impossible financial burden.

Under present conditions T.T. herds exist only because there are so many non-T.T. herds which give an outlet for "rejects." The Government should provide the market for these and liquidate them. Most of them could be spotted before being impregnated and fed for beef. Our Government might usefully follow the example of the U.S. Governments and compensate the farmers up to two-thirds of the actual value of the rejects.—I am, etc.,

Blackpool.

PETER J. McKENNA.

The Medical Superintendent

SIR.—During the years between the passing of the Local Government Act, 1929, and the outbreak of war medical superintendents of municipal hospitals strove hard to improve the efficiency of their hospitals. New departments were built; the medical and nursing staff augmented in numbers and in quality; the trappings of "Bumbledom" ripped off and everything made more seemly. The success of these efforts was shown in the thanks of harassed general practitioners whose patients could be given immediate admission, the gratitude at

the patients who were quick to appreciate the change, laudatory notices in the medical press, and faint praise from the voluntary hospitals. So far so good. The best municipal hospitals, it was generally acknowledged, were probably equal in standards of treatment (the only true criterion) to the best of the voluntary hospitals.

With the advent of the "period of planning," however, a change has come over the scene. Strong criticism of municipal hospitals and of medical superintendents has come from voluntary hospital sources, both lay and medical, apparently because it is feared that the Government may decide to place all hospitals under local government control and install medical superintendents in the voluntary hospitals. I, for one, sincerely hope that the Government do nothing of the kind, for if voluntary and municipal hospitals were given equal status and opportunities I am convinced that within a few years the latter would fully vindicate themselves in the eyes of the public, who, after all, are the judges in the long run.

Of particular interest is the criticism of medical superintendents, which comes mainly, I note, from London voluntary hospital consultants. I do not venture to speculate on the reasons for this curious geographical grouping of the critics. In your own columns Dr. Geoffrey Bourne has expressed himself trenchantly in articles, and in letters. Dr. Bourne is always interesting when treating of semi-philosophical generalizations, but in tilting at medical superintendents he shows that he is ignorant of his facts and has gained his knowledge at second hand. He should know that medical superintendents as a body wish to see their hospitals adequately staffed, clinicians assuming full clinical responsibility for their patients and protected by the medical superintendent from all interference from local politicians in their professional work. For the most part this is the existing state of affairs. Exceptions there may be, but in voluntary hospitals one has seen the most flagrant examples of clinical interference when the chief of a unit was on bad terms with his assistant. Of this Dr. Bourne should be well aware.

The Medical Superintendents' Society, of which I have the honour to be president, has formulated rules for the guidance of its members and local authorities, setting forth the relationship between superintendents and the other members of the hospital staff. While the medical superintendent is senior administrative officer of a hospital, he is not responsible for the actual treatment of all the patients but only for ensuring that they are afforded treatment by the medical staff. In a voluntary hospital it is taken for granted that the patients are adequately treated, but we all know that that is not always the case. The society considers that a certain proportion of the clinical work (bearing in mind his other duties) should be allotted to the medical superintendent, and this should be the only work, apart from administration, for which he should be responsible.

I am sure that attacks on municipal hospitals and their administrators will do little to promote the good of the voluntary hospitals and may well have different results from those expected. It would be easy to criticize the shortcomings of voluntary hospitals—everyone is aware of them—but members of municipal hospital staffs have largely refrained from doing so. Would that a similar restraint were exercised by our critics.—I am, etc.,

W. A. RAMSAY,
Medical Superintendent.

Crumpsall Hospital, Manchester.

Sterility and the State

SIR,—The purport of this letter is to draw attention to certain important aspects of sterility—such as can be done in a brief communication—inspired by recent discussions in both Houses of Parliament, by numerous questions from Members, and particularly by the lengthy debate in the Commons on July 16. The fall in the birth rate and the problem of Britain's declining future population have become the tasty bone of contention of Parliamentarians and sociologists with little or no real or intimate knowledge of the problems of infertility, either voluntary or involuntary. Lord Dawson and Dr. Edith Summerskill have, however, had their say and brought much stratospheric dialectics down to earth.

Family allowances, either at a flat rate as proposed in the Beveridge report or on a sliding scale as urged by Harrod

of Oxford, importation of the cream of Hitler's victims from the population of Europe, and the building of a social system in which women can have both a career and motherhood: among the main plans which have been suggested to combat the "silent revolt" against maternity. But the fact that there are nearly one million involuntary barren marriages (so it can be estimated) in Great Britain seems to have escaped notice. The gynaecologists in this country, and especially those of us who conduct special clinics for the investigation and treatment of sterility, are under no illusion as to the large numbers of infertile couples who seek a family and have been unsuccessful. The numbers seeking medical aid are rising throughout the country. The following are the year totals of women who come to the Royal Samaritan Hospital for Women, Glasgow, complaining of the total infertility of their marriage: 1938, 393; 1939, 387; 1940, 378; 1941, 319; 1942, 505; 1943 (first half), 318.

What is the explanation of the marked increase in the year 1942 and 1943? It has been suggested by Miss Rathbone and others that a good many women find pregnancy a convenient way of avoiding war service. Sir Wm. Fletcher Shaw, President of the R.C.O.G., is reported as saying that this is incorrect and that the majority are really conscientiously desirous of a family. I have tried to investigate this point as accurately as is possible by closely interrogating a consecutive and selected series of 200 "sterility patients." The number was admitted that evasion of war service was wholly or even a slight degree responsible for their complaint of infertility amounted to 26—i.e., 13%. If this figure can be accepted an approximately correct one and indicating the percentage complaining of sterility who endeavour to evade the Ministry of Labour's order that "any childless wife with no household responsibility is liable for war work," then some other factors are responsible for the increase. One of these, in my experience, is the general increase in the number of out-patients, which makes the apparent large jump in "sterilities" not quite so great, relatively—namely, in 1943 the total of new out-patients at the Royal Samaritan Hospital for Women was 3,706, but in 1942 the figure had risen to 4,446.

Another factor is the separation of husband and wife, either actual for short periods or impending, which often has the effect of stimulating the desire for parenthood and encouraging impatience. This is illustrated in one way by the increase in the percentage of couples complaining of infertility and who are married less than one year. This figure rose from 4.1% in a consecutive and unselected series of cases (500) before the war to 8% during the past year. Still another factor is the public's increasing knowledge of the value of expert treatment—in effect, this tends to make more and more seek advice without inquiring acceptance of a barren fate and a reticence based on a kind of modesty are both disappearing. The sooner the public gets to know that most sterility clinics (and experienced gynaecologists) successfully treat more than 30% of their cases the better it will be.

The whole problem of infertility is obviously one of the greatest importance to the State. The Government must take an active part in the planning and financing of the work. The Family Planning Association and the British Social Hygiene Council are doing valuable pioneering and deserve nothing but praise. But involuntary infertility must be the State's responsibility and, at the same time, opportunity.—I am, etc.

Royal Samaritan Hospital for Women,
Glasgow.

ALBERT SHARMAN.

Kienböck's Disease

SIR,—I was interested to read the two cases of Kienböck's disease of the semilunar (Aug. 14, p. 200) since I have recently seen bilateral Kienböck's disease in a girl at the unusually early age of 17. Attention was first drawn to the condition by increasing pain and stiffness of the left wrist following injury in which there had been forcible palmar flexion of the wrist. On examination it was found that both flexion and extension were severely restricted, the total movement of the wrist being little more than 10 degrees. There was some swelling of the dorsum of the wrist, and tenderness sharply localized over the back of the semilunar. X-ray examination showed gross abnormality of the semilunar, which was

terably flattened, with irregularity of all articular surfaces. The general density of the bone was much greater than that of the other carpal bones, but there was considerable unevenness of the texture, and some fragmentation was present. In view of this finding radiographs were also taken of the right wrist, and showed similar but less marked changes in the lunate. The bone was flattened, with rough articular surfaces, while the density was greater than that of the adjacent bones. There was no fragmentation on this side, though the bony texture was uneven. There was no history of injury to the right wrist, and the condition had given rise to no signs or symptoms. It would therefore seem that though trauma had aggravated the condition of the left wrist it was not the sole factor in the aetiology; but I was unable to obtain evidence of a septic focus.

It would be interesting to know if radiographs of the apparently normal wrists in the two cases reported by Mr. Officer Gordon also showed changes in the semilunar, since the similar condition of Köhler's disease of the tarsal apophysis is not infrequently bilateral.—I am, etc.,

Maryport, Cumberland.

J. D. H. BIRD, F.R.C.S.

The Teaching of Dermatology

SIR.—Brig. R. M. B. MacKenna, in his timely communication (Aug. 14, p. 191), states that "the standard of dermatological knowledge of recently qualified medical men is not proportionate, as it should be, to the incidence of cutaneous diseases in both civil and military practice," and he suggests the creation of a diploma in dermatology as one way out of a situation which reflects small credit upon the medical curriculum. Before the last war it was no uncommon thing for a medical student to graduate having put in only the most perfunctory attendances at "skins," which, for some strange reason, was seldom a popular subject. He is perfectly right in his contention that skin disorders "are statistically and economically of great importance," in both war and peace, and he rightly laments that self-prescribed or advertised remedies appear to be increasingly used by a suffering public.

First, I can personally testify that the nucleus of an examination requiring a high standard of knowledge of skin diseases already exists in the competition for the Chesterfield Silver Medal in Dermatology, instituted some years ago at the St. John's Hospital for Diseases of the Skin (London School of Dermatology), and were this, or some similar examination, to be sponsored by one of our universities with the power to grant not a "D.D." but a "Dipl. Derm.," men would not be found wanting to "keep alight the torch" of dermatology. Secondly, it may not be generally known south of the Tweed that a candidate for the M.R.C.P.E.d. may select dermatology as his "special subject in which a high standard of proficiency is required," and this examination demands a very thorough knowledge of the specialty, comprising as it does written papers, together with clinical, histological, and viva voce tests.—I am, etc.,

Ringwood, Hants.

G. NORMAN MEACHEN.

Maintenance Dose of Digitalis

SIR.—In his paper on maintenance treatment with digitalis (June 5, p. 694) Dr. A. S. Rogén proves that patients who have been in heart failure and have required digitalis are in need of a maintenance dose of the drug in order to prevent a recurrence of failure. This view is fairly widely accepted, but the author was impelled to re-examine the matter as the result of a statement by Gold to the effect that only 15% of the cardiac population requires digitalis. Rogén's finding that all the patients of the group he studied required digitalis implies a disagreement with the above statement. Gold's observations were based on the fact that of all people who have heart disease only about 15% have heart failure. These are the patients that require digitalis and constitute the group which Rogén studied—namely, patients who had been in the hospital with "definite signs of cardiac failure." There is, therefore, no real discordance between Rogén's findings and the statement by Gold that only 15% of the cardiac population requires digitalis.—I am, etc.,

Cornell University Medical College.

HARRY GOLD.

Obituary

DONALD ALEXANDER COLES, M.R.C.S., L.R.C.P.

We regret to announce the death, at the age of 88, of Dr. Donald Coles, formerly chairman of the Advisory Medical Committee of the Industrial Welfare Society and of the Council of Industrial Medicine.

Donald Alexander Coles received his medical education at St. Bartholomew's Hospital, where he was house-surgeon, house-physician, and ophthalmic house-surgeon, having qualified L.S.A., M.R.C.S., and L.R.C.P. in 1879. For a number of years Dr. Coles was medical officer to the Gas Light and Coke Company, and was a pioneer in industrial medicine in this country. At one time he was honorary secretary and Associate Editor of the *Journal of Industrial Hygiene*.

We are indebted to Prof. EDGAR L. COLLIS for the following appreciation: Few of us are privileged, before being called hence, to complete our life's work. Such, however, has been the lot of Donald Coles, essentially a Londoner, though his family sprang from Burgie in Morayshire. Always actively busy, no call to crowd even further work into time apparently already bespoke was ever refused. A veritable encyclopaedia of knowledge, he was always ready to acquire more, and revelled in learning from his juniors. He was an untiring attendant at meetings, and we were wont to tell him that his obituary notice would be: "He's gone to a meeting." Now it has come true; for he has gone to meet his life's dear companion with whom he kept their golden wedding. When the last great war drove him from Jerusalem, where he was attached to the English hospital, he came back home to London, bringing with him great knowledge of Eastern lore and marvellous Oriental rugs which seemed unusual in his Beckton home in East London. There he threw himself into the field of industrial medicine which was just seeing its birth, working for the Gas Light and Coke Company. His delightful personality and ever-present charm soon carried him to the front. A perfect chairman: without Coles presiding no international congress abroad on industrial accidents and diseases, or meeting at home discussing some technical aspect of the same subjects, seemed complete. At length in the fullness of years he had perforce to forgo coming to meetings, where his presence was ever missed, and his passing will now be recorded with deep regret and sorrow. Truly, a great gentleman has left us.

Mr. T. E. A. STOWELL, chairman of the Advisory Medical Committee, Industrial Welfare Society, writes: Death has removed a much-loved and gracious personality from the world of industrial medicine in the passing of Donald A. Coles—affectionately known as "dear old Coles." He was a leading pioneer in industrial medicine, and his advice was as gladly given as it was eagerly sought by his younger professional brethren who were interested in medicine in its application to the problems of industry. For a number of years Dr. Coles was medical officer to the Gas Light and Coke Company—a popular figure in the many international congresses on industrial medicine, and, up to the time of his death, a member of the Council of the Industrial Welfare Society.

GEOFFREY HOLMES, M.B.

The sudden death of Geoffrey Holmes, which took place at his home in Matlock on Aug. 16, came as a great shock to his wide circle of friends and has left a gap in the ranks of practitioners of physical medicine in general and hydrotherapy in particular which will not readily be filled.

Geoffrey Holmes received his medical training at Cambridge and afterwards at St. Mary's Hospital, qualifying as B.Ch. in 1910 and M.B. in 1911. He filled the posts of house-physician at St. Mary's and house-surgeon to the Hampstead and North-West London Hospital, and then became house-physician to the Devonshire Hospital for Rheumatic Diseases in Buxton, an appointment which directed his attention to the study of rheumatism and its treatment by physical methods, and this became his life's work. At the completion of this appointment Holmes decided to practise in Buxton, but very shortly afterwards, in

1914, he was among the first to join the R.A.M.C.; he served in France till 1917, when his health broke down and he was invalided out of the Service. Although this breakdown left him with a permanent disability which seriously handicapped his physical activities, he took up private practice in Harrogate almost immediately in order to free another doctor for service, and at the conclusion of the war he continued in practice there in collaboration with Dr. Edgcombe. Holmes quickly built up a large general and spa practice and served on the staff of the Harrogate Bath Hospital, to which institution he rendered notable service. He took a live interest in the B.M.A. and became president of the Yorkshire Branch. Always keen on physical methods of treatment, he was an active member of the Section of Physical Medicine of the Royal Society of Medicine and became its president; he was also a member of the Scientific Advisory Committee of the Empire Rheumatism Council and other scientific societies. He studied deeply the place of hydrology in the treatment of disease, and when the University of Leeds set the example of founding a lectureship in the subject he was appointed to it and continued to hold it till the time of his death. In 1938 he was offered the post of senior physician to Smedley's Hydropathic Institution at Matlock, and as he was beginning to feel the strain of private practice he accepted it and devoted himself more exclusively to hydrotherapy. A member of the Spa Practitioners Group and the Physical Medicine Group of the B.M.A., Holmes became chairman of the latter a few months ago, bringing to this new office the energy and enthusiasm which always characterized him. Early in the present year he was invited to join the staff of the Devonshire Hospital for Rheumatic Diseases in Buxton, and combined this with the oversight of the Smedley Memorial Hospital, to the advantage of both.

Holmes had a hatred of humbug of any kind and was often very outspoken in his criticisms, but at the same time he was the soul of good fellowship, and his friendship was shared and valued by a large circle. Those who did not know him well often failed to realize that beneath his love of the good things of life, both material and spiritual, was an intense keenness for his profession and especially for that specialty to which he had devoted himself. Handicapped by the physical breakdown which ended his Army career, he was obliged to forgo the open-air pursuits of his earlier years, but in their place he became an enthusiastic fly-fisherman, and no mean exponent of the art; he had been a member of the Flyfishers Club for many years.

JOHN MURRAY, F.R.C.S.

Mr. John Murray, consulting surgeon to the Middlesex Hospital, died at the age of 80 on Aug. 16.

Born at Monkstown, Co. Dublin, the son of a Dublin solicitor, John Murray was educated at Repton and Dublin University, where he graduated B.A. in 1884, and took the M.B., B.Ch. in 1886. He was house-surgeon to the London Temperance Hospital in 1887, and in 1890 took the F.R.C.S. and also became casualty surgical officer to the Middlesex Hospital, a post he held for 3 years. He was then successively surgical registrar, assistant surgeon in 1896, and surgeon to out-patients. He was Dean of the Middlesex from 1902 to 1908. Mr. Murray was also consulting surgeon to the Hospital for Hip Diseases, Sevenoaks, surgeon to St. Saviour's Hospital, and consulting surgeon, Paddington Green Children's Hospital. In the last war he was captain, R.A.M.C.(T.), and was attached to the Third London General Hospital at Wandsworth. He was the author of an article on surgery of the thorax in the *International Textbook of Surgery*. Mr. Murray married twice, and had one son and one daughter.

PROF. C. M. CAMPBELL, M.D.

News has just been received of the death in the U.S.A. of Dr. C. Macfie Campbell, professor in psychiatry in the Harvard Medical School since 1920, and medical director of the Boston Psychopathic Hospital.

Charles Macfie Campbell was born in Edinburgh in 1876, and was educated at George Watson's College, Edinburgh, and University, where he graduated M.A. in 1897, B.Sc. in 1900, and M.B., Ch.B. in 1902, proceeding to the M.D. in 1911. After studying in Paris and Heidelberg, Campbell then returned to

Edinburgh, where he was for a time resident physician in the Royal Infirmary. Nearly 40 years ago he went to the U.S. and was appointed assistant physician in the Psychiatric Institution, Ward's Island, New York. He later held a similar post at Bloomingdale Hospital, White Plains, New York. He was subsequently associate professor of psychiatry in Johns Hopkins University, and it was then that he became a naturalized American. Prof. Campbell was a pioneer in psychiatric treatment, taking a special interest in child delinquency. His views and his writings were well known to psychiatrists in this country, and at the Centenary Meeting of the British Medical Association in 1932 he read before the Section of Mental Medicine a paper entitled "The General Practitioner's Approach to his Nervous or Mental Patients"; this was published in the *Journal* of Dec. 31, 1932. In his book, *Destiny Disease in Mental Disorders*, he stressed the danger in psychiatry of diagnostic terms, and insisted that what was most important was the formulation of a case "in terms of forces of human life based on the painstaking dynamic analysis of the patient in his relation to the environment." His attitude was well illustrated in the title of another of his books: *Human Personality and the Environment*. He married in 1908 Jean Deans Rankin of Glasgow, also a doctor. Mrs. Campbell died a few years ago. They are survived by three daughters and a son, who is serving with the United States Forces.

E. C. SMITH, M.D., M.R.C.P.

We regret to announce the death through enemy action of Dr. E. C. Smith, Medical Research Institute, Lagos, W. Africa. Edward Cyril Smith qualified M.B., Ch.B. Dublin in 1921. Two years later he took the D.P.H. and in 1924 proceeded to his M.D. He took the M.R.C.P. in 1936. He was early interested in tropical medicine, and in 1927 took the D.T.M.&H. For a time he was pathologist at Sir Patrick Dun's Hospital and Mercer's Hospital.

The tragic death of E. C. Smith by enemy action, writes a colleague, is an irreparable loss, not only to his many friends—and he had a genius for friendship—but to the whole Colonial Medical Service, of which he was one of the brightest stars. There are few aspects of pathology in West Africa which Smith's work has not helped to illuminate, while his *Atlas of Skin Diseases in the Tropics* and his *Pathology and Bacteriology for Medical Students* will long remain essential books for all those who treat illness south of the Sahara. It is therefore not surprising, though official recognition lagged behind, that Smith had earned for himself an international reputation, so that hardly a medical officer of whatever nationality who found himself in Lagos failed to make the pilgrimage to the Medical Research Institute at Yaba. When war came Smith was most anxious to join the Army, but it was only too obvious that his work at Yaba was of the utmost importance, not only for the health of the civilian population but for the Army Medical Services themselves. When these services were still in embryo Smith's help with media, vaccines, and, above all, advice was invaluable. In addition he most efficiently organized classes in tropical medicine for all newly arrived Army medical officers. Yet it is not only as a competent pathologist that Smith should be remembered. He was perhaps at his best in his garden, with his roses and flowering shrubs, or in his bungalow, surrounded by his dogs and books, listening to the music he adored. He was one of the most generous and he was one of the most unassuming of men. West Africa is the poorer for his passing.

SIR BECKWITH WHITEHOUSE

Major R. D. G. VANN, R.A.M.C., writes: It came as a great shock to read in the *Iraq Times* of the sudden death of an old teacher and friend, Sir Beckwith Whitehouse. By those of us who had been his students in the Birmingham Medical School and General Hospital "Becky" was regarded with genuine affection. He was an excellent teacher, whether in O.P.D., ward, or theatre. He had the ability to impart to an audience his wealth of knowledge and experience with a command of English that was a delight to hear. He could always produce that touch of wit or the *mot juste* which went so far in forcing home the point he wished to make. We shall miss him, his impressive personality and dignity, his sense of humour but, as long as memory is left to us, we shall not lose him.

No. 31

EPIDEMIOLOGICAL NOTES

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 7.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of the Infant Mortality Rate, for: (a) The 126 great towns in England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland. The 13 principal towns in Eire. (f) The 13 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Discussion of Table

In England and Wales the incidence of infectious diseases continued to fall—scarlet fever by 459 cases, measles by 359, whooping-cough by 282, diphtheria by 116, and cerebrospinal fever by 13. The figure for acute pneumonia was higher by 52 and that for dysentery by 23.

The biggest drops in the totals of scarlet fever were Yorks West Riding 79, Lancashire 67, London 55, Staffordshire 42; and for measles, Lancashire 60, Monmouthshire 58, Northumberland 46, Essex 34. There were 84 fewer cases of whooping-cough in Yorks West Riding and 35 fewer in Warwickshire, and there were 14 fewer cases of diphtheria in Lancashire.

The rise in acute pneumonia was due to Lancashire and Yorks West Riding, with 21 and 26 cases respectively more than last week; with these exceptions there was no change in the general incidence.

Cerebrospinal fever, with 34 notifications, has fallen in incidence to a pre-war level for the first time since the end of 1939.

The seasonal rise in acute poliomyelitis has begun; 16 cases were recorded—the highest total since last autumn.

No sizable fresh outbreak of dysentery was reported during the week, but there were increases in existing outbreaks. The chief centres of infection were Lancashire 18 (Salford C.B. 10); Gloucestershire, Bristol C.B., 17; Shropshire, Oswestry R.D., 14; London 13; Cumberland, Border R.D., 10.

In Scotland there were 34 more notifications of diphtheria. The chief centre of infection was Glasgow, with 60 cases. The number of cases of dysentery fell by 65, but the incidence is still high at 95. The largest totals were Kincardine County 19, West Lothian County 17, and the cities of Aberdeen 14 and Glasgow 12.

Diphtheria

During the week the notifications of diphtheria in England and Wales fell below 500. The lowest weekly totals in the three years 1940-2 were 589, 674, and 572. The incidence of diphtheria during the present year has been lower than in the corresponding period of recent years; the notifications in the first 31 weeks of the six years 1937-42 expressed as a percentage of the number in 1943 were 109, 137, 101, 133, 178, and 145. The experience of the large towns suggests that the case fatality has also decreased. The number of deaths per 100 cases in the large towns during the first 31 weeks of 1940-3 were 5.5, 5.8, 4.2, and 4.0.

During the week reviewed the largest county totals were Lancashire 91, Yorks West Riding 55, Durham 42, and Staffordshire 30. These four Northern counties accounted for 44% of the total notifications in the country.

The Week Ending August 14

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,558, whooping-cough 1,855, diphtheria 491, measles 1,476, acute pneumonia 346, cerebrospinal fever 46, dysentery 149, paratyphoid 6, typhoid 10.

The Services

Capt. (Temp. Major) R. M. Johnstone, Capt. J. J. Hogan and J. G. S. Holman, R.A.M.C., Capt. N. A. Subramaniam, I.M.S., and Capt. C. Arumainayagam, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the Middle East.

The Efficiency Decoration of the Territorial Army has been conferred upon Lieut.-Col. J. G. Morgan, Majors A. M. Jones, T.A.R.O. (ret.), I. H. Lloyd-Williams, M.C., J. O. Moffat, and H. W. L. Nichols, all R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Prisoners of War.—War Subs. Capt. B. H. M. Aldridge, R.A.M.C., War Subs. Capt. W. T. G. Atkins, R.A.M.C., Acting Major R. C. Burgess, R.A.M.C., War Subs. Capt. C. Rigby, R.A.M.C., War Subs. Capt. L. D. Stone, R.A.M.C., Acting Col. J. Taylor, O.B.E., R.A.M.C.

Yorkshire has three orthopaedic hospitals for children, but there is no provision for treatment after the child reaches school-leaving age unless the condition is tuberculous. It is estimated that the county needs about 800 beds for children and 250 for adults; at present there are fewer than half of this number for children and practically none for adult cripples.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on July 24 the following medical degrees were conferred:

M.Ch.—J. P. Childs, *A. N. Guthkelch.
B.M., B.Ch.—J. M. Rice-Oxley, G. D. Bolsover, G. S. Dawes, A. Roper.
G. Gordon, R. D. K. Levy, *P. Shubik, *T. C. Bradshaw, *C. W. Bartley,
*J. H. Cumberland.

In a Congregation held on July 31 the following medical degrees were conferred:

D.M.—R. H. Gardiner.
B.M., B.Ch.—J. E. French, M. Weatherall, A. A. C. Dutton, G. J. Fraenkel,
Mrs. C. M. Phillips, E. C. Mercer.
*In absentia.

ROYAL COLLEGE OF SURGEONS OF ENGLAND
CORRECTION

In the *Journal* of Aug. 14 (p. 218) the Diploma in Ophthalmic Medicine and Surgery was, owing to a printer's error, wrongly described as the Diploma in "Orthopaedic" Medicine and Surgery.

Medical News

The British Medical Students Association has arranged a series of lectures on war surgery, to be given at University College Hospital Medical School at 4.30 p.m. every Wednesday as follows: Sept. 1, Mr. A. Tudor Edwards on "Wounds of the Thorax"; Sept. 8, Major-Gen. C. Max Page on "Surgery in the Field"; Sept. 15, Mr. A. H. McIndoe on "Injuries of the Face"; Sept. 22, Col. Elliott C. Cutler, U.S.A., on "American Views"; Sept. 29, Mr. H. J. B. Atkins on "Burns"; Oct. 6, Surg. Rear-Adml. G. Gordon-Taylor on "Sea Injuries and Problems of Shipwrecked Seamen." Two previous lectures were by Sir James Walton on "Recent Advances in the Treatment of War Wounds" and by Prof. J. Trueta on "The Biological Treatment of War Wounds and Fractures." The series is open to members of the British Medical Students Association only. Tickets, price 1s. for all, or any, of the eight lectures, are available from the B.M.S.A. representative in each school.

A meeting of the Colour Group of the Physical Society will be held at 2.30 p.m. on Thursday, Sept. 9, at the Science Museum, Exhibition Road, London, S.W.7, when a paper on the theory of colour photography will be read by Mr. J. B. Reid.

A meeting of the Royal Eye Hospital Clinical Society will be held at the hospital, St. George's Circus, Southwark, S.E., on Friday, Sept. 24, at 5.30 p.m., when a talk will be given by Mr. V. E. Negus, M.S., F.R.C.S., on the relationship of ophthalmology and rhinology.

On Aug. 23 Mrs. Rebecca Strong, O.B.E., at one time matron of the Glasgow Royal Infirmary, celebrated her hundredth birthday. Mrs. Strong received her early training at St. Thomas's Hospital, London, and from the Dundee Royal Infirmary went to Glasgow, where in 1895 she started a training school for nurses. She retired from active work thirty-five years ago, but in 1929 went to Montreal to address the International Council of Nurses.

Sir Felix Cassel has endowed a number of bursaries to be held by State-registered nurses desiring to take a short intensive course in modern methods of psychological treatment. The greater part of the course, which altogether will last 16 weeks, will be taken at the Cassel Hospital for Functional Nervous Disorders, but four weeks will be spent in London in visits to child guidance clinics and other centres of psychiatric interest. The bursaries, which will be administered by a committee under the chairmanship of Sir Farquhar Buzzard, will provide £4 10s. a week, out of which students will have to pay their living and training expenses, tuition being free. Inquiries should be sent to the Secretary, The Cassel Bursaries, Ash Hall, Bucknall, Stoke-on-Trent.

The first Wellcome Junior Fellowship for Veterinary Research has been awarded by the joint advisory committee of the Wellcome Foundation and the Veterinary Educational Trust to Mr. John Lochiel McGirr, B.Sc., M.R.C.V.S. The fellowship is tenable for one year at £400 per annum and can be renewed for a further one or two years at the discretion of the advisory committee. Another fellowship of equal value will be awarded in April, 1944.

A new physiotherapy department has just been opened at Malvern Hospital. It is hoped that this will become a centre for the treatment of rheumatism.

Dr. Allan Watt Downie, who since 1940 has been pathologist in charge of the Emergency Public Health Laboratory at Cambridge, has been appointed professor of bacteriology at Liverpool University.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are accepted to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required as proof is not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON, 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Alitology Western*, London; SECRETARY, *Medicra Western*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshough Gardens, Edinburgh.

ANY QUESTIONS?

Treatment of P.M.A.

Q.—What is the latest treatment for progressive muscular atrophy, I am working in India, and have a patient, a 15-year-old girl, whom I have tried vitamins B and E, massage, and sinusoidal faradic currents without success.

A.—Reference to the latest literature shows that there is no convincing evidence that any vitamin therapy benefits wasting of muscle, and carefully controlled experiment shows that vitamins E and B are without effect in progressive muscular atrophy. Similarly physiotherapy has at best a palliative effect. Progressive muscular atrophy is very unusual in a girl of 15, but if the diagnosis is certain there is no specific treatment which will in any way modify its course.

"Postural" Headache

Q.—A patient complains of headache on the top of the cranium during the daytime, but can manage to do his work. On going to bed at night the headache becomes so intense in about a couple of hours that the patient feels "as if the skull was going to burst" and the eyes become bloodshot. There is vertigo when he lies down to turn in bed from one side to another, and also when he gets up from the bed. What is the cause of this postural headache and vertigo, and what is the line of treatment?

A.—The question does not give sufficient information as regards physical examination, blood count, blood pressure, x-ray examination of the skull, etc. Hyperaemia from hypertensive polycythaemia would first be suspected. Hypertensive headache may be relieved by elevation of the head of the bed. The symptoms are also a little suggestive of a type of headache described by Horton (*J. Amer. med. Ass.*, 1941, 116, 377) as occurring in middle-aged or elderly patients, tending to awaken the patient shortly after he has fallen asleep and lessened by sitting or standing erect. This type of headache, however, is usually hemicranial in distribution and associated with the presence of swollen temporal vessels on the affected side. It can be relieved by a course of treatment with small doses of histamine diphosphate.

Laryngoscopy

Q.—What is the technique required in passing the directoscope invented by Haslinger of Vienna? Is it still a useful instrument?

A.—The directoscope of Haslinger is a self-retaining speculum which exposes the entrance to the larynx. It is a modification of Killian's suspension laryngoscope, but in suspension laryngoscopy a gallows is needed from which the speculum is suspended, while the directoscope when opened is self-retaining, the position of the patient being the same in either method. The principal advantage claimed was that it leaves both hands of the operator free as it does not require to be held in the left hand, as does the ordinary endoscopic speculum or tube. It does, however, stretch the cords of the pharynx rather tightly, and this is probably the reason why the apparatus is no longer fashionable. It is, presumably, as useful now as it ever was, and is capable of giving a good view of the larynx, but, as with suspension laryngoscopy, there are some cases in which the anterior commissure of the larynx is not exposed and for this an endoscopic tube must be used.

The Safe Period

Q.—What are the limits of the so-called "safe period"? I am often asked this question by patients who, for religious or other reasons, wish to avoid contraceptives.

A.—The "safe period" is based on the knowledge that ovulation usually occurs about fifteen days before the onset of a menstrual period—i.e., on the twelfth to fourteenth day of a 26- to 30-day cycle, counting from the first day of the last menstrual period.

etermination of the "safe period" in any individual demands accurate knowledge of the average length of the cycle and requires careful records over many months. The time of ovulation is then ascertained by subtracting fifteen days from the expected onset of the next period. The fertile period covers the eleven days made up of the five days preceding and the five days following the expected date of ovulation: e.g., the eighth to eighteenth days of an average 28-day cycle, first to eleventh days of an average 21-day cycle, and thirteenth to twenty-fifth days of an average 35-day cycle. The days of the cycle outside these limits constitute the "safe period."

The time of ovulation, however, is not so constant as to make the "safe period" absolutely safe, and conception has been recorded on any day in the cycle. But it is relatively safe, particularly in women with regular menses.

Cadaver Body Temperature

Q.—Occasion may arise when one is called upon to express an opinion as to time of death in a body. Apart from other signs, rate of post-mortem cooling is given in textbooks of medical jurisprudence as of importance. *Brend*, for instance, gives the rules: "to 3° F. per hour for first 5 hours, then 1° F. per hour following p. 32, 1934 edition). No mention is made as to how this temperature is taken. The ordinary clinical thermometer registers down to 5° F., but supposing a body has been dead 4 to 5 hours one would require a thermometer registering lower degrees. Is the use of an ordinary household thermometer, placed in the axilla, practicable as giving a reading, or, if not, what method does one use to estimate the body temperature of the cadaver?"

A.—The rate of cooling given in textbooks of forensic medicine cannot be more than a rough approximation owing to the number of factors to be considered. These are the state of nourishment and age of the body; the nature and amount of clothing; whether the body is in a room or out of doors, in a draught or in still air; and the temperature of the air. A clinical thermometer is of little use, and it is not advisable to take the temperature in the axilla. An ordinary tube thermometer should be used per rectum. The body temperature and the room temperature should be taken as soon as possible and the time of death worked out from all the data available.

Fragilitas Ossium

Q.—Is any treatment likely to benefit a frail boy aged 7, suffering from fragilitas ossium, and what is the prognosis?

A.—"Fragilitas ossium," or "osteogenesis imperfecta," is a condition characterized by the ease and frequency with which bones are fractured. The excessive fragility is due to a defect in the activity of osteoblasts, which is often manifest in intra-uterine life and involves bones from cartilage as well as those formed in membrane. Occasionally the condition is hereditary, when the patients generally have blue sclerae, which in some children may be marked without any undue bony weakness. The clinical picture varies with the number and site of fractures, and may resemble superficially those of rickets and achondroplasia. The x-ray appearance is quite sufficient to differentiate it from either of these diseases. The tendency to spontaneous fracture varies considerably, as also the rate and degree of effective bony healing. If fractures occur readily the prognosis is poor as regards general fitness, since severe distortion of the skeleton, with crippling, may result. In some patients the tendency to fracture diminishes in later years.

Metabolic and biochemical studies have failed to throw further light on the pathogenesis, aetiology, or therapeutics of this disease. It has been suggested that there is a deficiency of phosphatase (a ferment of importance in the laying down of lime salts in bone), especially in the subperiosteal area; but this finding has still to be confirmed, and, even if true, it is probably only a reflection of diminished osteoblastic activity. Unfortunately no specific treatment is known. Vitamin D, calcium salts, ultra-violet irradiation, and other therapeutic measures have been tried without noticeably affecting the progress of the disease. For the patient in question one would advise (1) making certain of the diagnosis; (2) as careful handling as possible in order to prevent fractures; (3) carefully regulated exercise and massage; and (4) a good general diet. Care in these directions may sometimes tide the patient over until a natural improvement occurs. This is well worth hoping for, but there is no x-ray, biochemical, or other test by which it can be foreseen.

Blood W.R. in a Child

Q.—What method or methods do experienced doctors recommend in taking blood for Wassermann (a) in infancy, (b) in childhood? Is the Behring venule satisfactory for infants and children, or is a serum syringe preferred? What percentage, if any, require an anaesthetic for successful withdrawal of blood?

A.—In infants it is usually best, after applying a tourniquet to the leg or thigh, to prick the heel with a triangular needle or make a small incision with a sharp scalpel. Quite often it is possible to obtain blood from one of the veins of the scalp, or from the

anterior jugular vein, with a syringe and fine needle; puncture of the superior longitudinal sinus has been done but it is not recommended. In children it is usually fairly easy to obtain blood from a vein in the antecubital fossa; if this is impossible one of the methods mentioned above should be employed.

The use of a Behring venule as opposed to a syringe is a matter of taste; the latter is more easy to manipulate, particularly if it has a peripheral nozzle and a really sharp needle is used. It should rarely, if ever, be necessary to employ an anaesthetic to obtain a specimen of blood; it is wise to enlist the services of a nurse to hold the infant or child and exclude the mother from the room during the operation.

Gynaecomastia

Q.—A stoker aged 21 has moderate gynaecomastia of which he is very self-conscious. Will it improve without treatment? What can be done with Roentgen radiation? Is this dangerous? Could surgery achieve a result without a scar having the same mental results as the original lesion?

A.—"Gynaecomastia" is the term usually applied to the excessive growth of the breast or breasts in the male. It may or may not be associated with endocrine disorders, and the morbid anatomy is that of chronic interstitial mastitis. It occurs as a transitory phenomenon in adolescence in a small percentage of normal males. Experimentally, enlargement of the breast may be produced by oestradiol, progesterone, pituitary "mammoth" hormone, testosterone, desoxycorticosterone, and extracts of the adrenal cortex. Clinically, the disorder may be associated with neoplasm of the testes, or adrenal cortex, or pituitary; with atrophy of the testes; and with cirrhosis of the liver, which normally deactivates oestrogens.

In spite of an obvious hormone origin in a particular case, only one breast may appear affected. The treatment is that of the endocrinopathy, where such exists. In idiopathic cases testosterone has been used empirically. The writer has no experience of radiation therapy, but surgical excision has been undertaken with success.

Prevention of Midge Bites

Q.—Is there any successful method of warding off midges and other biting insects? They are apt to cause much distress among e.g., forestry girls. Has there been any experience with Stockholm tar? Is it efficacious, and is it likely to cause dermatitis? If chemical repellants are inefficacious, is the use of materials such as butter muslin and chiffon acceptable?

A.—Many applications are employed to ward off midges and biting insects. These mostly contain an aromatic oil such as oil of citronella, eucalyptus, or oil of cajuput, but since these oils are volatile the effect in hot weather is transitory, and occasionally irritation results. Colloidal sulphur is noxious to many small insects. The following lotion is useful: phenol: t. viij; thymol. gr. v; tinct. iod. mit. j; aq. camphor. ad. j. This solution not only repels the insects for some hours but is excellent to relieve the irritation and inflammation of bites. Solution of coal tar, 5% in lead lotion or calamine lotion, is useful too. Whatever is used, watch should be kept for any personal idiosyncrasy to the application, or a dermatitis will ensue. A protective net of butter muslin worn round the head would, of course, be very effective, if acceptable by the wearer.

Professional Secrecy

Q.—Could you give me any advice on a question that is being raised with increasing frequency these days. It is a point in connexion with professional secrecy which arises when inquiries are made about patients who have been in the hospital where I am registrar. Some of these inquiries are made by non-professional people such as Army officers, and they are written on official forms suggesting that replies are expected and usually obtained. Some only require office details, but others demand a whole medical history. One instance recently was a request by a regimental paymaster for dates of admission and prognosis of a woman whose husband, a soldier, was applying for extra allowance. The questions which arise are these: Am I obliged to answer these inquiries? and, Is there any safeguard against redress sought by persons concerned?

A.—The duty of secrecy is owed by the doctor to his patient. It is quite distinct from any obligation which binds him to be discreet in matters concerning his professional colleagues or hospital. It is necessarily abrogated by the patient's consent, given freely and with full knowledge, or by a legal or moral obligation. In the example given, the request is made by an official, presumably in accordance with regulations and in the patient's own interests. The doctor's duty to his patient is surely first to satisfy himself that the official needs the information to comply with the law, and that to give it is in the patient's interests; and, secondly, to explain the situation fully to his patient and ask her consent. This should be put in writing and signed if the doctor fears that some day the patient may repudiate the consent; but it is worth noting that no doctor has ever been sued before any English court for breach of confidence (one Scots case was reported many years ago). The doctor should

then give precisely what information is required of him. He has thus done his duty to the patient, which includes a duty of disclosure in such cases as this. Where the giving of the information will not help the patient's interests, the doctor should not give it without satisfying himself that he is bound to give it by law—not merely that the inquirer is bound by law to ask him for it. He should ask the inquirer to state the legal authority under which he asks, and verify it himself or seek the help of a colleague better able to do so.

Pyretotherapy for Arthritis

Q.—I should be glad to have details of intravenous T.A.B. therapy for the purpose of hyperpyrexia. The patient is a professional man, of the apprehensive type, suffering from gonococcal rheumatism of two months' duration. The original infection was 20 years ago. Before the onset of the acute arthritis he had a urethral discharge. Smears and cultures were negative. C.F.T. \pm . E.M. 1. Admitted. Response to chemotherapy, irrigation, and vaccines was disappointing. Threads were still present in first glass. Ankles and knees swollen, with starting pains. Prostate tender, not enlarged. Recent massage begun. Temperature occasionally 99° F. in the last three weeks. No instrumentation and no physiotherapy carried out. Immediate prognosis appears poor.

A.—If the complement fixation test was carried out in a reliable laboratory and gave only a doubtful (\pm) result, it is very unlikely that the case is one of true gonococcal arthritis; it is more probably an "infective" arthritis due to some other organism, in which case the prognosis is less favourable. The first step is to give regular prostatic massage, noting the effect on the expressed secretions; if available, diathermy to the prostate is likely to be helpful. Intravenous T.A.B. therapy is not without danger. It should only be given in circumstances where skilled nursing and the means of combating shock and other complications are readily available. The initial dose should be 25 million organisms; subsequent doses will depend on the degree of reaction produced by the preceding dose or doses. For the second dose 50 millions, and for the third 100 to 150 millions, are usually adequate; the interval between injections should be three days. Alternatively, it has been found more effective to give an initial dose of 25 millions and a second one, also 25 millions, during the height of the fever produced by the first. By this method higher and more prolonged temperatures are usually obtained.

Technique.—Put the fasting patient to bed between blankets as soon as the first injection has been given; when shivering starts put a hot-water bottle in the bed and add more blankets. When free perspiration takes place give the patient plenty of 0.6% saline to drink and change his pyjamas as soon as they get wet. Give the second dose of vaccine when the temperature has risen to about 100° F., usually about four hours after the first. The patient can as a rule be allowed to get up on the following day. The doses of vaccine should be specially put up in sealed ampoules by a pathologist in order to ensure correct dosage and absolute sterility.

Prognosis in Epilepsy

Q.—A boy aged 11 has had frequent and severe epileptic fits for seven years, often two a day even on large doses of luminal. Three months ago the fits suddenly stopped and they have not returned, even though the patient has been off sedatives for the past two months. What is the prognosis in this case? What further precautionary measures should be taken? Incidentally it was exactly three months ago that I took swabs to see whether he was a diphtheria carrier, and the swabs turned out to be positive.

A.—It is not unknown for epileptic fits which have been frequent to stop for a while, with or without any anticonvulsant treatment. In a case of this sort the treatment should be continued for at least three years after the last fit. In a boy who started to have fits at the age of 4 years, and who has had them in spite of large doses of luminal, the chances of their recurring are very great. Observation of large numbers of epileptics shows that fits tend to occur in cycles, and it may well be that when this boy's attacks start again he will at some future date have another period when he is relatively free. The fact that he is a diphtheria carrier is merely a coincidence.

A Point of Nomenclature

Q.—In standard Latin-English dictionaries "valgus" is given as meaning "having the legs bent outwards, or bow-legged," and "varus" as meaning "having the legs bent inwards, or knock-kneed." In modern surgical terminology "genu valgum" means "knock-kneed" and "genu varum" means "bow-legged." How has this reversal of the original meaning come about?

A.—In genu valgum (knock-knee)—classical term *varus*—the knees are bent inwards, and the lower ends of the legs (tibiae or hank bones) are splayed outward. In genu varum (bow-legged)—classical term *valgus*—the knees are bowed outward, and the distal ends of the tibiae or leg-bones are inclined inward. It seems clear

from the following quotation—*hunc varum distortis cruribus* (H)—that the adjective used refers to the legs and not to the knees. apparent reversal of the meaning of the Latin words *valgus* *varus*, which has taken place in the modern use of these words with reference to the knees, may have arisen from the desire of surgical writers to specify clearly the particular part of the limb which is bent outward or inward in these two conditions, at the same time to emphasize that the deformity involves the including the adjoining epiphysal ends of the femur and tibia

INCOME TAX

Two Years' Tax in One Year

J. H. holds a temporary Government appointment. Income is being deducted from him in a manner which in effect means that he will have to pay two years' tax in one year. Has he any redress?

* * Tax on Government salaries, etc., is payable on the current year's basis and is deductible within the year in which the income is earned. What has apparently happened is that the assessors of the Department in which J. H. is serving was late in making necessary arrangements for tax to be deducted. (We assume J. H. made the appropriate declaration and claimed any allowance due to him within a reasonable time of being supplied with form of return.) Legally there is no redress, but we recommend J. H. to write to the Controller of Departmental Assessments, Hydro, Llandudno, North Wales, stating the facts and asking some part of the burden to be spread forward.

LETTERS, NOTES, ETC.

Total Loss of Hair

Dr. H. HALDIN-DAVIS writes: I see in "Any Question" (July 31) that one of the *B.M.J.* "Brains Trust" states that loss of hair is usually the result of shock or acute anxiety. I much doubt if this be true. I have seen numerous cases of alopecia in children in whom there was no question of shock or anxiety. It is well known that in the syndrome known as "alopecia areata" there is every gradation in severity from a single small transitory patch of baldness to complete alopecia of the scalp even disappearance of the hair on the body. It is a disease prone to run in families, and I recall a well-known legal family which there were several cases, and one member delayed exhibited his tendency to becoming subject to this condition until he was past 70 years of age. But when he did so he became completely bald within a few weeks, and in his case there was no question of shock or anxiety. To anticipate critics I will add that his baldness was not of the ordinary senile description. It began with patches which speedily spread and coalesced, producing the typical billiard-ball effect. But I regret to say that I was not able to follow the case long enough for it to be of any help in assisting the correspondent as to the prognosis in the case of his schoolmaster.

Wanted: Tapeworm Segments

Prof. R. M. GORDON, Department of Entomology and Parasitology, School of Tropical Medicine, Pembroke Place, Liverpool, 3, writes: We are anxious to obtain segments of the tapeworm *Diplobothrium latum* in connexion with some experimental work we are doing here in Liverpool. The best way to forward the segments would be to place a little damp, but not soaking wet, cotton wool at the bottom of a small screw-top bottle, then to drop in the segments and fill up the remaining space with more damp wool. Of course, I would be only too glad to defray the cost of postage.

An Appeal for Back Numbers

Members who do not preserve the *Journal* for binding are invited to send their copies (preferably in bulk) to B.M.A. House, Tavistock Square, W.C.1, addressed to the Secretary of the *Journal*. The cost of carriage will be repaid. There is a constant demand for back numbers, and each issue goes quickly out of print; hence spare copies published during the war will be welcome. The growth in membership to a figure well above 43,000 has increased the circulation of the *Journal* by 12% in the past four years, but every new member must have his weekly copy. Meanwhile there has been a very severe and progressive cut in the amount of paper allowed to be used for printing. Every means of economizing has been adopted in order to make the paper ration go as far as possible, and nothing more can be done except to reduce the number of pages still further. A member who returns his copies at an early date after reading them will in that way put them back into circulation through the Head Office. If the response to this appeal is spread the help thus given will be very material at a time of increasing difficulty.

THE Rh FACTOR AND ERYTHROBLASTOSIS FOETALIS

AN INVESTIGATION OF 50 FAMILIES

BY

R. R. RACE,* M.R.C.S., L.R.C.P. G. L. TAYLOR,* M.D., Ph.D., M.R.C.P. D. F. CAPPELL, M.D.

AND

MARJORY N. McFARLANE, M.B., Ch.B.

(From the Galton Laboratory Serum Unit, Department of Pathology, Cambridge, and the Pathology Department, University of St. Andrews and Royal Infirmary, Dundee)

Recent American work has shown that iso-immunization plays an important part in the aetiology of erythroblastosis foetalis, a familial disease of the newborn, which Parsons, with justification, thinks would be better called "haemolytic disease of the newborn."

The part played by iso-immunization in this condition has been described at length by Levine, Burnham, Katzin, and Vogel (1941) and by Boorman, Dodd, and Mollison (1942). In their view, erythroblastosis foetalis results from iso-immunization of the mother to a red-blood-cell antigen present in the foetus, inherited from the father but absent in the mother herself, and the subsequent passage of the mother's immune agglutinins through the placenta to act on the susceptible blood of the foetus. In most cases described by the above authors iso-immunization to the Rh blood-group factor appeared to be responsible, as more than 90% of the mothers were Rh-negative and an antibody to the Rh factor was found in the serum of many of them. The Rh factor is inherited as a dominant character. Whenever it was possible to examine the blood of an erythroblastic baby of an Rh-negative mother it proved to be Rh-positive. The finding that more than 90% of mothers of erythroblastic children are Rh-negative when only 15% of the normal population are Rh-negative is in itself so overwhelmingly significant statistically that a connexion between the Rh groups and this disease can hardly be doubted, even apart from the evidence provided by the detection of the antibody in many of the cases.

It can be shown that in one pregnancy in ten the mother is Rh-negative and the baby Rh-positive, and that in one pregnancy in five the mother has an agglutinin for an antigen of the A-B-O system of groups present in her foetus. Haemolytic disease of the newborn is, however, much rarer than would be expected if iso-immunization and placental transmission of harmful agglutinins from mother to foetus occurred in every instance in which the possibility exists. It is obvious, therefore, that there is yet much to be learned about the way in which iso-immunization operates in such families. The subject is undoubtedly of importance in obstetrics and in paediatrics, and while at the moment it is not clear what facts may prove of importance in extending our knowledge, it is essential that no opportunity of making serological investigations should be lost.

The object of the present paper is to put on record our findings in the examination of 50 families in which erythroblastosis foetalis has been diagnosed, and a list of their pedigrees forms the main part of this communication. The cases have been sent to us by practitioners and pathologists from many parts of the United Kingdom and from Northern Ireland, and in those reported it seems reasonably certain that the diagnosis of erythroblastosis foetalis was correct. The material is far from complete, for the great difficulties always present in the

pursuit and investigation of human families are in wartime enormously increased. For instance, men and women are away from home in the Forces; travelling is difficult; and, with doctors so fully occupied, personal visiting is practically impossible. Nevertheless, much information has been gathered together, and some of it may well prove of value to future workers. The technique used for detecting the Rh factor and its antibody has been described by Taylor (1943).

Results

Of the 50 mothers 6 were Rh-positive and 44 were Rh-negative; while in the sera of 38 of these Rh-negative women anti-Rh agglutinins were found. If Rh were not concerned in the causation of erythroblastosis foetalis only 7 or 8 of these 50 women would be expected to be Rh-negative; that 44 were Rh-negative and that Rh antibody was present in the serum of the great majority confirms the connexion between this recently discovered blood-group factor and the disease. In spite of the absence of demonstrable anti-Rh agglutinins in the remaining six Rh-negative cases it is highly probable that iso-immunization of the mother to the Rh factor played a part; the absence of anti-Rh may in some of them have been due to the length of time since delivery, which on the average was four years as against less than a year for the 38 cases in which antibody was found. In none of the six was there any certain evidence of other blood-group factors being involved. That as many as six of the twelve mothers in whose serum anti-Rh was not found were Rh-negative strongly suggests that Rh was concerned.

While Rh is the blood-group factor most commonly involved in the causation of erythroblastosis foetalis, it appears certain that other red-cell antigens may behave in a similar way. As mentioned above, in one pregnancy in five the mother's serum contains an iso-agglutinin for an antigen of the A-B-O system of groups present in her foetus. (This will always be so where the foetus is of group AB, save in about one case in six in which the mother will also be of group AB.) In such a heterospecific pregnancy the mother's natural iso-agglutinins might perhaps cause the destruction of her child's red cells. Even when the mother is Rh-negative iso-immunization to some antigen other than Rh might be concerned in the causation of erythroblastosis. For example, in one case recently studied (but not included in the 50 cases of this series) the mother was of group A,B Rh-negative and her husband and baby were both A, Rh-positive; anti-Rh agglutinins were present in good amount in her serum, but in addition a very strong alpha₁ agglutinin (with A, Rh-negative cells titre at room temp. 128-256, at 37° C. 32) was also present. It would appear that this woman had become iso-immunized against both A₁ and Rh contained in the cells of the foetus, for the strength of the alpha₁ was greater than we have found in grouping more than 100,000 persons (see Taylor, Race, Prior, and Ikin, 1942). It seems probable that the erythroblastosis from which her baby suffered may have been due to placental transmission

 The last three represent diagnosis as reported to us.
 49 of the 50 families in this table were mentioned by Taylor (1943).

of both these agglutinins. When the mother is Rh-positive it seems certain, if iso-immunization is responsible, that another antigen must be involved. In 6 of the families in the above series the mother was Rh-positive, but in only one of the 6 (No. 26) were we able to examine the blood of the affected child. Both mother and child were O Rh-negative; the father O Rh-negative; obviously in this case the A-B-O groups could not be involved. We were able to examine the blood of the husbands of only two of these six Rh-positive mothers; both these men were Rh-negative. Since then, however, we have examined two further cases of Rh-positive mothers with affected children; in one the husband was Rh-negative, in the other he was Rh-positive. In this last case the serum of the mother (group O Rh-positive) contained a very powerful antibody more active at 37° C. than at room temperature. This serum gave clear-cut positive reactions with the red cells of 80% of a large number of unselected group O persons, including her erythroblastotic child (group O Rh-positive). When tested against group O Rh-negative bloods it was found to agglutinate strongly a series of 50 consecutive samples. After removal of the anti-A and anti-B iso-antibodies the serum still agglutinated the husband's cells (group A₁ Rh-positive). This antibody is not specific for any of the blood-cell antigens A, B, O, M, N, P, Rh, but it is suspected that it is similar to the irregular agglutinin found by Levine, Javert, and Katzin (see Levine, 1941) in the blood of an Rh-positive mother with Rh-negative husband and an erythroblastotic child, and named by them anti-Hr. According to Wiener (1942) this irregular agglutinin acts on Rh-negative cells and certain Rh-positive cells, which he designates Rh₂ on the analogy of the subdivisions of the A group. The work of Davidsohn and Boharsky (1942) indicates that the subdivision of the Rh factor is much more complex than this, and our experience bears this out. We are of the opinion that our finding of three out of four husbands of Rh-positive mothers with affected children to be Rh-negative is significant, and similar cases have been recorded by Javert (1942a, 1942b). These latter families are not among the 50 reported in this paper; it is hoped to publish further details about them when more information is available. It is possible that mistakes in diagnosis may contribute to the small group of families with Rh-positive mothers. For example, this series of families originally included one with a child at first thought to be erythroblastotic but which was later shown to have acholuric jaundice. Such a family, really not erythroblastotic at all, if mistakenly included in a series

of erythroblastotic families would in six cases out of seven fall into the group where the mother is Rh-positive, for there is no reason why mothers of, say, acholuric babies should not have the normal distribution of Rh groups.

There are other points arising from our findings that have interested us very much. In particular, we have failed to find a single Rh-negative child among the offspring of these 4 Rh-negative mothers; we have tested 33 healthy and 16 affected children. The absence of Rh-negative children from the healthy group is highly significant, and may be provisionally explained by two circumstances, both favourable to the predominance, among families showing the condition, of those of which the fathers are homozygous. There is reason to think (1) that all Rh-positive children of Rh-negative mothers are not equally liable to the disease—

In most families two or three positive children seem to be necessary before an affected child is produced, and where the father is homozygous (RhRh) and all his children are positive, these conditions are more likely to be met than when he is heterozygous (Rrh) and there is an equal chance that each conception may produce Rh-positive or Rh-negative children;

(2) that ascertainment is more frequent when the affected child has an affected sibling than when it is the only affected child in the family.

It can readily be shown that, in the absence of unforeseen disturbances, approximately three out of seven Rh-positive males must be homozygous, while four must be heterozygous. Since half the children of the heterozygotes by Rh-negative wives must be Rh-negative, the proportion of these is two-sevenths of all the children of marriages between Rh-positive men and Rh-negative women. If, therefore, it was sufficient to determine haemolytic disease for a child of an Rh-negative mother to be Rh-positive, and if all such cases had the same probability of ascertainment, we should expect one-fifth of their sibs taking haemolytic and normal together, to be Rh-negative.

Of 5 Rh-positive children the sibs of 3 (those of homozygous fathers) would all be positive; of the other 2 positive children (of heterozygous fathers) half the sibs would be positive—i.e., of all the sibs of Rh-positive children four-fifths would be positive and one-fifth negative.

This expectation is clearly contradicted by our finding in this series—none negative out of 33 normal.

If, on the other hand, to take a second simple hypothesis for comparison with the facts, we suppose that a necessary

id sufficient condition for the appearance of the disease is at both the subject and the next prior sib must be Rh-positive. In single-child families would be excluded from the record, hile for all sizes of family greater than one the representation of families having heterozygous fathers would again be halved, that three families out of four would be the children of homozygotes. Of the children, excluding both the propositus and the child next preceding it, only one in eight would be expected to be Rh-negative. In our material this exclusion fit 26 children grouped for Rh; of these only 3.25 would be expected to be Rh-negative, which is not incompatible with the absence of observed cases.

The scarcity of Rh-negative children will have to be taken into consideration in estimating the chances of getting an h-negative (that is, an unaffected) child in such families. It has been possible to show, by finding an Rh-negative child, that the father is heterozygous, the chance of the next child being normal is one in two. In the absence of this indication prognosis is entirely unfavourable.

That an Rh-negative child may occur in an affected family as been shown by our finding very recently a family in which the first child was Rh-negative, the second Rh-positive, while the third died from jaundice. The blood of this child was not examined, but the mother was Rh-negative and her serum contained an anti-Rh agglutinin. In our present series, with one exception, no mother who has once produced an erythroblastic baby has ever had a normal surviving child. The exceptional child is the fourth of Family 15, and while we have been unable to obtain any evidence of his having been affected, he is Rh-positive, though only with certain sera. It is perhaps significant that his cells on several occasions failed to react with his mother's serum (on one occasion there was a suggestion of a weak reaction), whereas the cells of the first-born reacted strongly.

Of the first children borne by the 44 Rh-negative mothers 38 were unaffected, 5 were stillbirths or miscarriages, and 1 (No. 44) is known to have suffered from the disease. Although anti-Rh was not found in the mother's serum in this last case, it is likely that this factor was responsible, for the baby was O Rh-positive; so it does not seem possible that the A-B-O system of groups could have been involved. From the second birth onwards there was a steadily increasing ratio of affected to normal children. Four of the six Rh-positive mothers, on the other hand, had first children with the disease; two of these three were affected stillbirths. The earlier onset in this group might be due, if the A-B-O system of groups were responsible, to the iso-agglutinins being already present in the mother's serum, though in only one of the four cases is the father's group known to be such that a heterospecific pregnancy could occur.

In our series about a quarter of the children diagnosed as affected survived; three-quarters were born dead or died mostly within a week of birth. Although miscarriages and stillbirths not diagnosed as affected are not represented in these proportions it is probable that the same causes were operative in a substantial proportion; on the other hand, mild cases which recover may not find their way into such a series. Affected children were approximately evenly distributed between the two sexes.

We are grateful to the following pathologists and practitioners for sending us samples of blood and case details: E. F. Aubert, T. H. Boon, W. Broughton-Alcock, F. J. Burke, F. E. Camps, A. E. Chisholm, J. B. Cochrane, J. Craig, J. J. Dubash, Caroline A. Elliott, Margaret Fairlie, J. S. Faulds, A. Hanton, J. S. Hesketh, D. V. Hubble, P. H. Kendall, N. Lissimore, S. Lucas, A. J. McCall, S. G. M. Mackay, H. Mallinson, L. C. Martin, M. E. Matthews, S. F. Moores, J. Murray, G. R. Osborne, W. S. Stanbury, R. Williams, and C. H. Wrigley. We also wish to thank Prof. R. A. Fisher for help with the paragraphs dealing with the absence of Rh-negative children in our material.

HAEMOLYTIC DISEASE OF THE NEWBORN (ERYTHROBLASTOSIS FOETALIS)

ITS TREATMENT WITH RHESUS-NEGATIVE BLOOD*

BY

JANET D. GIMSON, M.B., B.S.

Resident Assistant Physician to the Hospital for Sick Children,
Great Ormond Street

A series of 19 consecutive cases of haemolytic disease of the newborn, collected during the eleven months from March, 1942, to Feb., 1943, at the Hospital for Sick Children, Great Ormond Street, is here surveyed. Following on the work of Levine *et al.* (1941a, 1941b) on the iso-immunization theory of causation of erythroblastosis foetalis, it was desired to treat these infants by transfusion with rhesus-negative blood, free of agglutinins, and thus test out the recommendation that rhesus-negative blood would produce better results than rhesus-positive blood. The blood of the infants and mothers was tested with this theory in view.

Briefly, the iso-immunization theory may be stated thus: A man whose blood contains the Rh factor mates with a woman whose blood does not contain the Rh factor. If her foetus is Rh-positive she may produce anti-Rh agglutinins as a result of immunization with the foetal blood. The antibodies pass through the placenta, and in suitable concentration cause haemolysis of the foetal red cells. Several workers—Wiener in 1942, and Boorman, Dodd, and Mollison (1942)—have shown that a little less than 15% of a random sample of the population have blood which does not contain the rhesus factor—namely, is Rh-negative. In 1941 Landsteiner and Wiener showed that the Rh factor is inherited as a dominant Mendelian character. The Rh-positive child of an Rh-negative mother inherits the factor from the father, and if the mother responds by making anti-Rh the foetus is likely to be affected by haemolytic disease. If in such a family the father is heterozygous (RhRh) each child will have an even chance of being Rh-negative and so of escaping the disease, but if he is homozygous (RhRh) every child will be Rh-positive and likely to be affected. The difference in clinical forms is probably due to varying degree and duration of iso-immunization during the course of pregnancy. Although immunization to the Rh factor appears to be responsible for the great majority of cases of haemolytic disease (Levine *et al.*, 1941a, 1941b; Boorman *et al.*, 1942) other group factors are, evidently responsible in cases where the mother is found to be Rh-positive.

The consequent anaemia in the foetus calls forth a great effort of response from all erythropoietic tissue. This has often been shown post mortem by previous workers, and is usually demonstrable in varying degree in the blood during life. Parsons, Hawksley, and Gittins in 1933, and Hawksley and Lightwood in 1934, laid stress on the fact that there was more evidence for there being a primary haemolytic cause for erythroblastosis than for a primary disturbance of blood formation. The possibility of a hereditary transmitted factor had not then been adequately investigated.

Present Series of Cases

This series of 19 cases (see Table) is necessarily a selected group of this disease. The selection is automatic and is therefore typical of those cases coming to any children's hospital which is not directly attached to a maternity hospital: for macerated foetuses and stillborn infants are not seen, and it is rare for cases of hydrops foetalis or icterus gravis neonatorum, which are fatal within 24 hours of birth, to be sent in before death. Seventeen were primarily cases of icterus, with or without anaemia; two were anaemic only and showed no jaundice. Two had transient oedema of the eyelids; one had ascites in addition to jaundice and pallor. One case appeared mentally defective. The age when admitted to hospital varied between 3 days and 6 weeks: 4 came within the first week of life; 13 within the first fortnight.

Family History.—Five had the classical history of previous fants born jaundiced and dying within a few hours or days of birth, or a child jaundiced at birth who survived (in some cases living only to be mentally defective or kernicteric), or of stillbirths or miscarriages. Four had the family history of what might be called physiologically jaundiced infants previously. Three were first babies. Seven had no pertinent family history: of these, three were only the second child, three were the third child, and one was the sixth child. In only one family was there a history in the grandparents' generation. It is difficult to get these questions answered accurately, as people are naturally uncertain about aunts or uncles or cousins who have had stillbirths. None of the mothers had ever had a blood transfusion; therefore no history of transfusion accidents could be obtained.

Blood Findings with Reference to the Rhesus Factor

In every case the blood of the mother and infant was tested for the rhesus factor.* All the mothers of this series were Rh-negative and all the infants were Rh-positive. Anti-Rh agglutinins were found in the mother's serum in all but one case. When this has been proved it is suggested that the mother should have some words of warning written on her identity disk or card, such as: "Please note in case of blood transfusion: I am Rh-negative." Thus it is hoped to prevent haemolytic transfusion reactions which would be anticipated should Rh-positive blood be used in these cases.

The serological findings may be of diagnostic assistance. In some cases of jaundice of the newborn it is impossible to be certain whether one is dealing with a mild example of haemolytic disease or with physiological jaundice. This has been acknowledged before by Parsons, by Hawksley and Lightwood, and by Mollison. There may or may not be enough haemoglobin to cause a dangerous fall in red-blood-cell and haemoglobin levels. Case 11 bears out this point: jaundice had been maximal on the second day, after which it had faded until the tenth day, and then increased slightly; by the fourteenth day, when the baby reached hospital, the jaundice was again waning. This, then, might have been considered a case of physiological jaundice. The serological findings showed the mother to be Rh-negative and the infant Rh-positive. Anti-Rh agglutinins were found in the mother's serum. The diagnosis of a mild case of haemolytic disease of the newborn was therefore established. Congenital obliteration of the bile ducts had to be considered in the differential diagnosis of Cases 17 and 18. They were interesting examples of biliary obstruction lasting for an unusually long time in this haemolytic disease. Here again the blood findings aided the diagnosis, the mothers being Rh-negative and the infants Rh-positive (Lightwood—awaiting publication).

Treatment

It is well known that a certain number of cases, even of icterus gravis neonatorum, will recover with no treatment; though Hampson in 1929 quoted an 80% mortality in a survey of untreated cases. On admission to hospital the clinical condition of the patient was considered and the blood picture determined. It was rarely thought necessary to transfuse unless the erythrocyte count was below 3.5 millions. Case 11 was therefore the one patient of the series who was not transfused. It is interesting, however, to debate whether it would not have been a good therapeutic measure to give a transfusion in this case. The haemoglobin level continued to fall slowly until the baby was 4 weeks old, and until then she was lethargic, difficult over feeding, and did not gain weight. At the age of 4 weeks the haemolytic process ceased to progress, the anaemia lessened, and the general condition improved steadily. In all probability this would have happened sooner had a transfusion of rhesus-negative blood been given. Cases 4, 6, 13, and 18 were watched for a varying period of 6 days to 7 weeks before deciding that transfusion was necessary. The others were transfused within 24 hours of admission.

The procedure has been varied as experience has accumulated. At the beginning of the series a transfusion of Rh-positive blood was given when the condition was such that it was unjustifiable to withhold treatment until the Rh picture

had been determined and a supply of Rh-negative blood had been obtained. However, in the first three cases, in which Rh-positive blood was used, there was evidence of continued and even increased haemolysis. An initial rise of haemoglobin and erythrocyte levels occurred, as was hoped for by previous workers who treated their cases with parents' blood. An increase in the jaundice and in the size of the liver and spleen was also noted. Within a few hours or days the haemoglobin and erythrocyte levels had fallen considerably and the infants were in need of further transfusion. The next transfusion was of Rh-negative blood. The rationale of giving Rh-negative blood free of agglutinins is that the foetal blood is Rh-positive and is undergoing destruction. It is desirable to give blood which is not so destroyed. (Chart I—Case 1—shows the

CHART I.—Case 1.

haemoglobin levels following transfusion with Rh-positive and then Rh-negative blood in the same patient. The level is not well maintained after the first transfusion, but is considerably better after the second.)

Further haemolysis of the patient's red cells is not prevented by giving Rh-negative blood. Blood is being provided, however, which will not be destroyed more rapidly than normal and on which the infant can live until the haemolytic process of the disease has come to an end. Haemolysis continued to occur, as seen by gradually increasing pallor and fall of haemoglobin (Cases 3, 5, 8, 10, and 12).

In a few cases mixed transfusions of Rh-positive and Rh-negative blood were given so that the survival rate of the two types of erythrocyte could be studied by Dr. Mollison. As reported by him in a paper read before the Medical Research Society in Oct., 1942, and not yet published, Rh-negative erythrocytes were usually found to survive for at least 90 days, whereas Rh-positive erythrocytes were often destroyed within a few days of transfusion. Because of these findings and because of the poor clinical results observed, it was felt unjustifiable to continue to give transfusions of Rh-positive blood. The later cases in this series therefore received Rh-negative blood exclusively. No increase of jaundice has been noticed following Rh-negative transfusion. When Rh-negative

CHART II.—Comparison with another series of cases.

blood only was used, more than two transfusions were not necessary. This compares favourably with Diamond, Blackfan, and Baty's results when up to six transfusions in a single case were given, with those mentioned by Hawksley and Lightwood when from one to four transfusions were given, and also with previous cases treated at this hospital.

* All serological tests were performed by Miss Boorman, Miss Dodd, and Dr. Mollison.

A comparison of the present series with the 17 consecutive cases of erythroblastosis foetalis occurring in this hospital between 1935 and 1941 treated by blood transfusion is shown in Chart II. It will be seen that in the latter series up to six transfusions were required in a single case. The deaths (only those from the disease itself or transfusion are included) numbered 6 out of the 17 cases. Four of these patients were kept alive, but in analysing their blood pictures it was found that there had been no improvement after transfusions. Seven cases finally did satisfactorily, whereas in the 1942-3 series all 18 regained and maintained normal blood pictures. Eleven cases of the present series received an initial whole Rh-negative transfusion. Eight of these required only one transfusion. Two bottles of Group O Rh-negative stored blood supplied by the Transfusion Service are now always kept in the refrigerator. This store is renewed fortnightly.

CHART III.—Comparison of two similar cases.

A comparison of two similar cases of the disease is shown in Chart III. They are alike in family history, both second children, sibling normal, and they both presented at hospital on the third day of life. 1938: Blood picture on admission—Hb 80%, R.B.C. 2.98 millions, no nucleated red cells seen. Therefore this presented as a milder case than Case 10. It is shown that in spite of three 80-c.c.m. transfusions (father's blood for first two, the third no specification) there is no improvement in the haemoglobin level; nor was there in erythrocyte count. On the 42nd day of life the infant is said to have developed diphtheria and its subsequent history is not known. Whereas the haemoglobin level of Case 10 was satisfactorily maintained after the second Rh-negative transfusion.

CHART IV.—Two other similar cases compared.

Chart IV shows another comparison of two similar cases. 1935: presented on the 13th day of life; sibling jaundiced, died on 10th day. Blood picture on admission: Hb 50%, R.B.C. 2.1 millions, erythroblasts 13%. From the blood picture on admission again it will be noted that this was apparently a milder case of the disease than Case 14. Six transfusions in all were given, but there was no arrest of the haemolytic process, and the infant died on the 20th day of life. Case 14 shows that the haemolytic process continued for two months after Rh-negative transfusion; but the haemoglobin level did not fall alarmingly, and the general condition of the patient was well sustained. After two months the haemoglobin and erythrocyte levels steadily returned to normal. Mollison found in Case 8 that 15 days after the first transfusion, which was of Rh-negative blood, the great majority of the circulating cells were Rh-negative—i.e., those of the donor. Had the transfusion not been given the infant would probably have been moribund.

Reaction to Transfusion

There has been only one case of reaction from transfusion (Case 12). Rh-positive and Rh-negative mixed blood fusion was being given. A total of 250 c.c.m. had been planned. By the time 100 c.c.m. had been given the jaundice increased considerably, the respirations were rapid at 60 per minute, and the pulse was thready and imperceptible at 100 per minute. Nikethamide 0.25 c.c.m. was given. The rate of transfusion had been reduced; however, it was considered inadvisable to continue beyond 130 c.c.m. The following day the jaundice remained deep but the general condition had improved. Thirt-six hours after the transfusion had been stopped the haemoglobin was 50% and the red cells 2.38 millions per c.c.m. A third strong Rh antibody had been found in the mother's serum. It was decided to give a whole Rh-negative blood transfusion of 200 c.c.m. No reaction occurred; the jaundice did not increase; but the haemoglobin 24 hours later was only 60% and the red cells 3.2 millions. Four days later the haemoglobin had fallen to 50% and the red cells to 2.86 millions. A third transfusion was given, of 260 c.c.m., this being the second entirely of Rh-negative blood. The general condition was much improved. The red cells were 4.71 millions per c.c.m. although the haemoglobin rose only to 70% forty-eight hours after this transfusion; it was still at this level a week later.

In this question of reaction after transfusion there is another interesting comparison to be drawn: the 1935-41 records show more often than not that a rise of temperature and some constitutional disturbance followed the transfusions. Also, as liver and spleen and in the depth of jaundice—the haemolytic process was accentuated rather than decreased. As already stated, only the one reaction has been witnessed, and this when giving mixed Rh-positive and Rh-negative blood. An increase of haemolysis has been observed in the present series from Rh-negative blood transfusion.

Size of Transfusion.—It will be noticed that larger transfusions have usually been given than were previously employed. The volume in c.c.m. to be transfused is calculated from the formula

$$\frac{\% \text{ rise of Hb required}}{100} \times \text{blood volume,}$$

the blood volume being approximately 88 c.c.m. per kilo of body weight (40 c.c.m. per lb.), calculated on expected weight for age from birth weight. This works out at more than 10 to 15 c.c.m. per lb., which was the old recommended rule. This had been a sound rule, as a reaction to transfusion was then such a frequent occurrence. These reactions could be explained on a haemolytic basis and therefore might have been more severe had larger amounts been employed.

All these transfusions have been given intravenously, by drip into the internal saphenous or a cubital fossa vein. It is aimed to maintain a constant rate of 15 to 20 c.c.m. per hour. The infants have been kept in hospital overnight after 1 transfusion.

Results

All these cases have been followed to the present date. Sixteen of the 19 are apparently normal. One (Case 3) died of fulminating bronchopneumonia at the age of 21 months; this was six weeks after the infant had regained a normal blood picture (and after it had been discharged from hospital).

Two cases were presumed to have brain damage. (No necropsy was performed, as these patients did not die in this hospital.) Both of them happened to have mothers with exceptionally high-titre antibodies in their sera. Both were severely jaundiced—one from the third, the other from the second day of life. The first baby (Case 6) was not admitted until 12 days old, by which time already its cerebral function was abnormal and spasticity was marked. Though the jaundice faded after the second transfusion and the anaemia was permanently relieved, no advantageous change occurred in the mentality or spasticity. This baby died in Nov., 1942, aged 5 months, of bronchopneumonia. The second baby (Case 2) was admitted aged 7 days. The jaundice was very severe and had become apparent on the second day. On the third day the infant had developed stertorous breathing and had become very weak. The erythrocyte count was only 1.8 millions, and

small transfusion of the father's blood (Rh-positive) was given -60 c.cm. (This case occurred early in the series.) The transfusion increased the jaundice; the blood picture, although immediately improved, was reduced to the original level in 36 hours. A second transfusion, of Rh-negative blood this time, as given, and a normal blood picture was thereafter maintained. Grave doubts were held as to the mentality of the infant from his 14th day of life, from which time he lay in marked opisthotonos and stared vacantly. No spasticity was noticed until the fifth month. The condition was thought to be due to nuclear jaundice. He died in Oct., 1942, of bronchopneumonia.

Rustin McIntosh (1941) quoted a kernicterus incidence of 0% in cases of erythroblastosis foetalis. In view of the fact that Fitzgerald, Greenfield, and Kounine (1939) state that it manifests itself within 24 hours of the jaundice, it is unlikely that this dreaded sequel can be avoided.

Recommendations

1. Blood transfusion with rhesus-negative blood free of agglutinins should be employed for the treatment of cases of haemolytic disease of the newborn. A relatively large transfusion is advocated when necessary, as no haemolytic reaction need be anticipated. The general condition of the infant is thus rapidly improved; a stay of only 24 hours in hospital with further out-patient observation can be allowed, and a minimum number of transfusions will be necessary.
2. A store of rhesus-negative blood free of agglutinins should be easily available to all paediatric units and maternity hospitals.
3. Pregnant women who have previously borne an infant thought to be affected with haemolytic disease should be tested for the rhesus factor. If Rh-negative, she should be delivered in a maternity institution where Rh-negative blood is available.
4. For an infant born jaundiced, with a strong family history of haemolytic disease, immediate transfusion with Rh-negative blood free of agglutinins should be given, no matter what the erythrocyte and haemoglobin levels.

Summary

Nineteen consecutive cases of haemolytic disease of the newborn have been treated and investigated with reference to the immunization theory of causation. Eighteen of these were transfused. Clinical comparison has been attempted between the effectiveness of rhesus-negative blood free of agglutinins and rhesus-positive blood. All these patients regained a normal blood picture with at most two Rh-negative transfusions.

These results are encouraging, and although the number of cases studied is small it would seem that if an infant with haemolytic disease of the newborn lives long enough to reach hospital there is a good chance of its survival.

Dr. Mollison and his co-workers at the Sutton Blood Transfusion Unit have done all the testing for the rhesus factor and supplied us with the Rh-negative blood used in the series. I should like here to thank him. My thanks are also due to the staff of the Hospital or Sick Children, Great Ormond Street, for their co-operation.

Mr. Herbert Morrison foresees the Prison Medical Service, of the future as an integral part of a new comprehensive health and medical service, but providing more opportunities for studying the mental aspects of crime. The Home Secretary, who was speaking to the Prison Medical Officers' Association, said that study of this kind was developing well until stopped by the war, but it had been found possible to resume it on a limited scale at Wormwood Scrubs. The number of prisoners in Britain had risen from 10,236 in 1939 to 12,400 in 1942, due largely to wartime offences. The incidence of certain diseases, especially venereal disease, had increased, but thanks to the efforts of the prison medical staff prisoners generally were healthier at the end of their sentence than when admitted.

OCCURRENCE OF THE Rh ANTIGEN IN THE POPULATION

NOTES ON 5 CASES OF ERYTHROBLASTOSIS FOETALIS

BY

EDWARD D. HOARE, M.D.

Department of Pathology, Welsh National School of Medicine

In a recent paper Boorman, Dodd, and Mollison (1942) gave a full account of our present knowledge of the Rh factor in the blood. The following is a record of its incidence in 1,122 unselected blood donors in South Wales.* A study of 5 cases of erythroblastosis foetalis is also included.

Technique

The test serum was obtained by immunizing guinea-pigs with rhesus monkey blood as described by Landsteiner and Wiener (1941). Only 3 out of 10 guinea-pigs yielded satisfactory results, but from the three sera were obtained which gave a clear-cut distinction between Rh-positive and Rh-negative bloods at dilutions up to 1:60—a titre high enough to avoid confusion from any anti-A or anti-B agglutinins that might be present. It should be stated that the serum was kindly tested by Dr. Mollison, who confirmed the presence of Rh antibodies, but considered their titre somewhat low and apt to permit of false negatives. Dr. Mollison, however, in testing the serum, used equal volumes of cell suspension with 1:60 serum dilutions, whereas in testing the donors' bloods 1 volume of cell suspension with 2 volumes of serum was always used, so that a greater antibody concentration was obtained. Results were read according to the "sediment pattern" after standing at room temperature, and after microscopical examination of the resuspended sediment (Landsteiner and Wiener, 1941). At a later stage in the work the serum and cells were allowed to stand at room temperature for 1/2 to 1 hour and were shaken and spun at 500 to 1,000 r.p.m. for 1 to 2 minutes; the deposit was then examined for agglutinates by gently tapping the tube. The results obtained by this method agreed with those given by the "sediment pattern" method.

Table showing Distribution of the Rh Antigen in 1,122 Unselected Blood Donors

Group:	AB	A	B	O	Total
Rh-positive	27	349	90	483	949 (84.6%)
Rh-negative	3	64	14	92	173 (15.4%)

The results correspond closely with those of Wiener (1942), who found 85.6% Rh-positive out of 777 persons of all groups, and of Boorman, Dodd, and Mollison (1942), who found 85.15% Rh-positive of 1,610 persons of Groups A and O.

Erythroblastosis Foetalis

Various observations by Levine and Stetson (1939) and Levine, Katzin, and Burnham (1941) have shown that an Rh-negative mother carrying an Rh-positive foetus (by an Rh-positive father) may become immunized to the Rh factor in the foetus and produce antibodies which destroy the foetal erythrocytes. A haemolytic anaemia results in the foetus, and is manifest in the newborn infant in the condition known as erythroblastosis foetalis. Five such cases have come under my notice in the course of this investigation.

Case 1.—Child aged 19 days; jaundiced since birth; severe anaemia. R.B.C. 1.25 millions per c.mm.; Hb 24%; moderate numbers of erythroblasts and normoblasts. Despite blood transfusion the child died. Father, Group A Rh-positive; mother, Group O Rh-negative; child, Group O Rh-positive. The mother's serum, taken 3 weeks after her delivery, reacted against 2 Rh-positive Group O bloods. There was no reaction with 3 Rh-negative Group O bloods. The Rh antibodies were apparently of the cold type, and were detectable in the undiluted serum at room temperature and to a titre of 1:4 at 0° C.

Case 2.—Child aged 2½ weeks; jaundiced since birth; moderately severe hyperchromic anaemia. R.B.C. 2.02 millions per c.mm.;

* Samples of blood were kindly supplied by Dr. Drummond of the Welsh Board of Health Blood Transfusion Service.

Hb 50%; erythroblasts and normoblasts present in moderate numbers. The child was treated by blood transfusion and recovered. Father abroad; mother, Group A Rh-negative; child, Group A Rh-positive. The mother's serum, taken 3 weeks after her delivery, reacted against 3 Rh-positive Group A bloods and gave no reaction against 3 Rh-negative Group O bloods. The titre of the antibodies was not determined.

Case 3.—Child aged 2 days; jaundiced since birth; moderately severe hyperchromic anaemia. R.B.C. 2.15 millions per c.mm.; Hb 48%; moderate numbers of erythroblasts and normoblasts. Blood transfusion was given, but the child died. Father, Group O Rh-positive; mother, Group A Rh-negative; child, Group A Rh-positive. The mother's serum, tested 4 weeks after her delivery, reacted against 11 Rh-positive bloods (2 Group A, 9 Group O), but gave no reaction with 9 Rh-negative bloods (2 Group A, 7 Group O). When titrated against 3 Rh-positive Group O bloods the serum reacted in dilutions up to 1:32.

Case 4.—Child aged 3 weeks; jaundiced since birth; moderately severe anaemia. Small numbers of erythroblasts and normoblasts were present in the blood film. The child died before any treatment could be given. Father, Group A Rh-positive; mother, Group A Rh-negative; child, Group A Rh-positive. The mother's serum, 2 weeks after her delivery, reacted against 14 Rh-positive Group O bloods—to a titre of 1:32 with two of them and 1:8 with one. There was no reaction with 2 Rh-negative Group O bloods.

Case 5.—Child aged 10 days; jaundiced since birth; very severe hyperchromic anaemia. R.B.C. 830,000 per c.mm.; Hb 27%; large numbers of erythroblasts and normoblasts seen. The child received blood transfusion, but died. Father, Group O Rh-positive; mother, Group A Rh-negative; child, Group O Rh-positive. The mother's serum, 2½ weeks after delivery, reacted against 6 Rh-positive bloods (2 Group A, 4 Group O). There was no reaction with 3 Rh-negative bloods (1 Group A, 2 Group O). The titre was 1:16 when tested against 3 Rh-positive Group O bloods.

In all the five cases described above the father and child were Rh-positive while the mother was Rh-negative. In all cases the mother's serum contained Rh antibodies, and in four of the cases its titre ranged from 1:1 to 1:32. Case 4 was of interest in that the titre was 1:8 with some bloods and 1:32 with others used for test purposes. Both the "sediment pattern" and the centrifuge method were used in the determination of the titre. They gave the same reading. In one case only was the antibody of the cold type.

I should add that at the time these cases occurred the reports that Rh-negative blood often survived longer in the circulation of cases of erythroblastosis foetalis than Rh-positive blood had not appeared, and as there was no theoretical reason against the use of Rh-positive blood, the Rh grouping of the transfused blood was not determined. A-B-O grouping and careful cross-matching tests were of course done.

My thanks are due to Dr. MacCallum of the Wellcome Bureau of Scientific Research, who kindly supplied me with rhesus monkey blood.

A NOTE ON THE REHABILITATION OF HEART PATIENTS

BY

BASIL PARSONS-SMITH, M.D., F.R.C.P.
Physician to the National Heart Hospital

As with all other branches of medicine, the aim of rehabilitation in heart disease is restoration of function and physical capacity to the fullest possible extent. For the achievement of such an objective it is essential that the general programme of treatment in cardiac patients shall include all such remedial measures as are likely to ensure the use of their physical capacity to the best advantage.

Fortunately the trend of modern opinion entirely reverses the long-accepted teaching which doomed patients with heart affections to a life of inactivity and permanent invalidism. We recognize in broad principle the varying degrees of debility

which cardiovascular diseases involve, but equally also appreciate the fact that in such conditions the circulatory reserve may be relatively well maintained. The practical demonstration of circulatory reserve or compensation is far to seek, for it is common knowledge that organic disease is frequently recognized during the casual examination of normally active individuals, and it quite often happens that patients with well-defined heart disease continue in strenuous employments and survive long professional careers of average duration. As expected, the records of such cases have provoked considerable interest, for they show conclusively that cardiac disease need not signify total incapacity and they adduce prima facie evidence that an efficient circulation can be maintained under favourable circumstances, in patients suffering from structural heart affections.

The significance of the term "cardiac reserve" has become increasingly apparent, and it is recognized nowadays as the essential pivot on which revolves the whole process of circulatory compensation, incidentally also all the problems of rehabilitation. Suitable preparations for their ultimate rehabilitation should be included automatically when formulating schemes of treatment for patients with circulatory affections, and there is good reason to assume that under favourable circumstances they may be permitted ultimately to enjoy all the economic advantages of appropriate employment.

Accepting these principles, the wide scope of our duty in regard to the management of cardiac cases becomes amply defined. We must not only be prepared to prescribe all the essential remedies that may be required by our patients during the initial stages of their illnesses but we must also assume full responsibility for their convalescence. We must envisage the time when they will be able to resume their original employment or, alternatively, we must be prepared to recommence educational training for some suitable occupation, our assessment in this respect depending upon the extent of such physical defects as may be present, the patient's age, temperament, and social circumstances. The intervention of Nature both in the cure and in the readjustment of cardiac patients cannot be too strongly emphasized. Assuming an average level of general health, we are justified in expecting that Nature, *per se*, will limit cardiovascular disease, that it will determine adequate compensation, and that, in general terms, it will promote a favourable prognosis.

Preludes to Rehabilitation

The natural development of compensation is obviously an essential prelude to rehabilitation, and the latter depends more particularly on the physiological capabilities of the myocardium. As the result of experimental research and clinical investigation we know that the pulse rate and the stroke volume increase during exercise and that the venous return to the heart is proportionately accelerated. These changes materially improve the range of the myocardial efficiency, it being a well-established axiom that, within limits, the greater the initial length of the heart-muscle fibres at the beginning of systole the more forcible is the subsequent contraction. Such considerations are of outstanding importance in the rehabilitation of patients convalescent from heart affections, the rational deduction being that in appropriate cases exercise and occupation promote the efficiency of both the cardiac and the circulatory functions.

It may be inferred from the above that heart patients require suitable exercise to maintain their general resistance and that according to their degree of compensation, their circumstances, inclinations, etc., some form of regular employment is, in all cases, a most desirable prescription.

A further and important factor in rehabilitation therapy is reassurance, the value of which cannot be over-emphasized. All classes of heart patients, particularly children, are naturally impressionable, and if encouraged in adequate fashion during the whole course of their illness they may be relied upon to assist materially their curative treatment and future prospects. Beside discussions concerning the gravity of any particular condition, its response or otherwise to treatment, the question of prognosis, and the possibility of complications should be avoided as a general rule. The heart-disease atmosphere should be obviated so far as is possible, and frequent examinations

the heart are not desirable, there being ample evidence—e.g., the sleeping pulse rate, the blood count, the sedimentation rate, the temperature chart, the general appearance, nutrition, etc.—on which for all practical purposes the disease process can be assessed.

The therapeutic value of assurance is far-reaching; it ensures encouragement and confidence of patients—also, incidentally, that degree of co-operation which is of vital consequence to their recovery and rehabilitation later. It may imply a certain amount of legitimate deceit, but it tends to stabilize the general environment of patients and obviates the development of neurotic symptoms which may be likely to supervene with the provocation in rheumatic children, whose temperament is often characteristically nervous in type.

The rehabilitation of children suffering from heart affections has been the subject of considerable investigation in recent years, and well-standardized schemes based on institutional methods have now been formulated. A comprehensive service for the welfare of children suffering from heart disease is provided in hospitals specially adapted for the purpose, where, in addition to constant medical supervision, the young inmates enjoy all the advantages of juvenile society in their programme of games and graduated exercises, and where, at the same time, facilities for general education and vocational training are also available.

Early Stages of Rehabilitation

In many respects the rehabilitation of adults is a more complex problem than it is in children. They have naturally an inborn dread of heart disease, frequently they are apprehensive regarding their supposed limitations for exertion, and, unless vigorously persuaded to the contrary in these respects, their introspective tendencies may rapidly mature into confirmed neuroses. Such, in point of fact, is more often than not the sequence of events in the group of cases nowadays listed under the title "traumatic heart disease." Admittedly the heart may be seriously injured as the result of accidents affecting the thorax, but in a considerable number of cases the diagnosis is built up on inconclusive evidence and perpetuated by litigation, with disastrous results to any chance of the patient's re-employment subsequently.

When, on the other hand, patients are reassured in the early stages of their illness, they visualize their future with an increasing degree of confidence, and under these circumstances their rehabilitation becomes a natural process. Suitable remedies, medicinal and otherwise, having been prescribed to alleviate the initial stages of the illness, and all urgent symptoms having subsided, a course of light general massage, with passive and later resistance movements at the larger joints, should be begun at the earliest possible moment. Assuming that the patient shows no sign of intolerance to this treatment he may cautiously begin a programme of graduated exercise. Having accommodated himself to the sitting position, first in bed and later in a chair, breathing exercises should be prescribed, and he may next be allowed to test his walking capacity on his bedroom floor, then about the house, and in due course out of doors.

After a varying number of weeks, or possibly months, the circulatory reserve becomes stabilized and the patient may be regarded as having achieved the primary or ambulatory stage of his rehabilitation. Continuing with light general massage and breathing exercises, he may now be allowed to extend his walks by degrees—first on the level, later on easy gradients—and, in general terms, to ensure the maximum of sunshine and fresh air. While the patient is symptom-free the graduated-exercise scheme may proceed in uninterrupted fashion, but any suggestion of intolerance—e.g., complaints of sternal pain, breathlessness, palpitation, faintness, fatigue, etc.—will need investigation, with some revision of the daily routine and probably, for a time, additional allowances of rest. Otherwise it frequently happens that the smooth convalescence of cardiac patients is materially delayed by some degree of obesity, and this condition should always be regarded as a complication of major importance. It constitutes a grave menace to rehabilitation therapy, and in a certain number of cases may be the one outstanding factor that perpetuates incapacity in heart patients and renders them unfit for employment.

Remedial measures should be taken at the earliest possible moment. Certain forms of physiotherapy—e.g., massage, graduated exercise, electrical treatment, recreational activities, etc.—are helpful in varying degree, and in conjunction with these it is essential that dietetic modifications should be included—e.g., a restricted intake of carbohydrates and fats, with fast days at regular intervals—also thyroid medication in adequate dosage if the basal metabolism happens to be subnormal.

Exercise and Recreation

In the absence of complications patients may be expected to evince in due course a natural urge to regain, through muscular activity, their normal range of physical fitness. As a general rule the first objective should be forms of exercise to which they were accustomed before their illness, also such games and amusements as may be in keeping with their age, physique, and personal inclinations. Certain principles, as follows, are fundamental to the question of exercise and recreation in recovered heart patients:

1. They must not involve extensive muscle-group exertion, either sudden or prolonged.
2. They must not admit of undue exposure to weather extremes or tests of endurance, and, except in mild degree, they must not include contests for athletic supremacy.
3. They must be regulated according to the exercise tolerance of each individual patient, which can be ascertained partly by objective examination, partly also by the patient's own description of his effort sensations.

Suitable Occupations

Having accommodated themselves to appropriate forms of exercise and resumed in other respects their normal routine of domestic habits, patients ultimately arrive at the final stage of their rehabilitation, implying that they are again capable of employment. In general terms recovered heart patients should choose moderately light occupations which do not entail sudden or prolonged physical effort, which admit of relaxation during the working hours, and which afford opportunities for reasonable allowances of fresh air and easy exercises. It may happen that the patient's previous employment conforms to these requirements, otherwise it will be necessary for him to choose an alternative occupation that will be appropriate to his diminished circulatory reserve and, at the same time, suitable to his personal qualifications and natural instincts.

Medical Memoranda

Misadventure under Convulsant Treatment

Treatment by electrically induced convulsions (I prefer the short word "electroplexy") is such a useful and, on the whole, successful treatment for depression that its various hazards should be well publicized.

CASE HISTORY

A youth aged 19 was brought to the out-patient department suffering from adolescent depression. He also had delusions of reference and hallucinations of sound and sight. It was thought that the florid symptoms were signs of a schizoid tendency uncovered by the depression rather than the signs of a primary schizophrenia. It was therefore decided to induce a convulsion once a week in the out-patient department.

On recovering from his third treatment he complained that his two upper central incisors were missing. Two bleeding sockets could be seen, and in their depths the stumps of the two teeth. The teeth themselves could not be found. The couch, the floor, the patient's clothes, the nurse were all searched and radiographs were taken of the chest and abdomen. The x-ray sister then suggested that the teeth may have been lost upwards; she had found a tooth lately in an antrum, where it had been driven by an uppercut. The patient's face was radiographed and the complete teeth were seen lying in the maxilla. On digital examination the roots could be felt protruding immediately above the gum. What had been taken for stumps on the first examination were really the crowns. The teeth had been driven up by the force of the tonic spasm in the second stage of the fit.

It is gratifying to report that the patient has recovered from the psychosis.

Reviews

A SYNOPSIS OF PATHOLOGY

Synopsis of Pathology. By W. A. D. Anderson, M.D. (Pp. 661; illustrated. 30s.) London: Henry Kimpton, 1942.

It is almost traditional to subject "synopses" to severe criticism. They are said to tempt the student to memorize "lists and tables" rather than read, learn, and inwardly digest the solid stuff of his textbook. In spite of this they are usually used quite legitimately for final revision immediately before an examination, and most of them can be used in no other way. They are almost unintelligible without considerable previous knowledge of the subject, they make desperately dull reading, and very few are illustrated.

None of these criticisms can be levelled against this book. It has all the merits of a good synopsis in that it is compact and of convenient size, it is full of easily accessible and skilfully condensed information, it is beautifully and lavishly illustrated, and, above all, it is readable. Great pains have obviously been taken to bring the subject-matter up to date. There is, for instance, a short chapter devoted to virus and rickettsia diseases, another to vitamin deficiencies. The chapters on the pathology of the breast, the female genital organs, and the nervous system are full and lucid. The author has not been content simply to describe recently recognized or uncommon conditions: in most instances a brief description is accompanied by photomicrographs which would be difficult to find outside the pages of monographs and journals. Each chapter is followed by a list of well-selected references, practically all of which are to American journals.

The scope of the book is certainly wider than that of a synopsis written for undergraduates and designed for pre-examination revision. In the preface the author expresses a hope that it will prove "useful to the clinician who must maintain familiarity with the foundation sciences of medical practice." We predict that this hope will be realized.

INTRODUCTION TO PSYCHIATRY

Psychological Medicine. A Short Introduction to Psychiatry. By Desmond Curran, M.B., F.R.C.P., D.P.M., and Eric Guttmann, M.D. With an appendix, *War-Time Psychiatry*. Foreword by J. J. Conybeare, D.M., F.R.C.P. (Pp. 188. 10s. 6d., plus 6d. postage.) Edinburgh: E. and S. Livingstone, 1943.

The elementary presentation of psychiatry is a formidable task. On the whole the authors have succeeded in presenting an account of modern psychiatry which the beginner should find helpful, but the value of the book lies less perhaps in its formal descriptions, which are of necessity very brief, than in its attempt to inculcate a sound orientation to the subject-matter, and thus the word "introduction" in the title is apt. More of a book of this compass cannot be expected. In the introductory chapter the student is made aware how widespread the psychiatric net is, and he is encouraged to see psychiatric problems not in terms of the crystallized chronic forms of the mental hospital, which is too often all he is taught, but as an important domain of human study with ramifications towards all sides, not least the sociological—a view which this war should surely impress on a relatively unpsychiatrically minded profession and public. There follows an admirable chapter on the elementary principles of what is sometimes called "structural analysis" and so-called "pluri-dimensional diagnosis." Descriptions of the different reaction types follow. These are conventional but sound. The section on psychotherapy will arouse little disagreement among those with a sound psychiatric training. The chapter on schizophrenia is somewhat disappointing, but to write a brief yet satisfactory account of this strange and intangible disorder is impossible. It might have been better to attempt a description in more general terms, concentrating on the so-called basic symptoms and illustrating the odd thought disorder with examples. The obsessional reaction pattern is, strangely enough, included in the chapter on affective reactions.

Modern treatment is given prominence. By far the most valuable part of this book, however, is the section on war

psychiatry. Here the authors speak with a vigour and sureness of touch which bespeak an intimate day-to-day acquaintance with the problems involved. These chapters should also assure the book a wide circulation. They should be read by all Service doctors. The section on prophylaxis is particularly good. One of the authors has devoted special study to the neuropsychiatric aspects of head injury, so that this chapter has a special authority. It is perhaps a pity that the author did not devote the whole volume to war psychiatry. authoritative presentation of this field is needed, and someone might be expected to enjoy more than ephemeral standing since these problems will remain with us for many a year. Psychiatrists without experience in the armed Forces might well find such a book particularly helpful. There are notable omissions in this section. Thus there is no account of "effort syndrome" or of the problems of malingering and responsibility and the so-called asthenic constitution, though all of these are daily concerns of the Service psychiatrist. A few remarks on the value of the electro-encephalogram would have been useful. Local authorities lax in implementing the provisions of the Mental Deficiency Acts should digest at least to heart the section on "the moron in wartime."

Lastly, this book has an unusual distinction. It is written by men of widely different schools, it can be described as a sound eclectic filtrate of modern psychiatric knowledge, and as such can be warmly recommended to the profession.

CHRONIC EPITHELIOID GRANULOMATOSIS

Der Morbus Besnier-Boeck-Schaumann. Chronische epitheloidzellige Resikulo-endotheliose sive granulomatose. By Dr. St. J. Leitner. (Pp. 139; illustrated. Fr. 2.50.) Basle: Benno Schwabe and Co.

This is an interesting study of a pathological condition which began to be recognized in 1889 when Besnier first described the condition known as lupus pernio or chilblain lupus. Later it was acknowledged that the cases described by Boeck as sarcoids or miliary lupoids were of the same nature, and subsequently Schaumann pointed out that the disease was by no means exclusively a skin disease. Hence Dr. Leitner considers it only just that its nomenclature should be associated with the names of all three observers. Pathologically it may be described as a chronic epithelioid cell granulomatosis. In addition to the skin it typically affects the parotid glands, the uveal tract, and the lymph glands, and produces swellings of the bones of phalanges. It is extremely chronic in its course, but may start at almost any age from infancy to extreme senility, and displays no preference for either sex. The problem of its aetiology has been much studied but without success. There is much about it to suggest a tuberculous infection, but we believe we are right in stating that in no case has the tubercle bacillus been demonstrated, and the results of animal inoculation have been far from conclusive. A large proportion of the cases have been reported from Scandinavian countries at one time localities affected by leprosy, and perhaps for this reason attempts have also been made to prove that this curious disease is an attenuated form of leprosy, but there is very little real evidence that such can be the case. It remains an unsolved problem.

Dr. Leitner has collated the work of previous observers and has added to it a critical description of some fifteen cases of his own. Both dermatologists and haematologists will find his remarks very interesting.

MEDICO-RELIGIOUS POLICY OVER-SEAS

The Wholeness of Man: A Study in the History of Healing. By Phyllis L. Garlick. James Long Lectures, 1943. (Pp. 202. 10s. 6d.) London: The Highway Press.

The title of this book is derived from the unity of human personality, which implies a vital relation between the healing of body, mind, and spirit—"health is wholeness; wholeness is health." In developing her theme the author has been aided by experts on the subject. The book begins with a good historical retrospect, from 2250 B.C., when the Babylonian Code of Hammurabi clearly indicated the existence of an organized medical profession, to the foundations of modern medicine and the evolution of medical missions which began about A.D. 1800. Medical science is perhaps the greatest benefi-

hat Western peoples have brought to the Orient, where fatalism and hopelessness had too often been the chief features of the traditional medical systems handed down the ages in an empirical manner. The extension of missionary organizations has led to the establishment abroad of communities trained to a sense of responsibility and care for the soul as well as the body. Though somewhat overweighted with philosophical speculation the volume crystallizes views on medico-religious policy over-seas, and will doubtless be of great help to medical missionaries of all denominations.

Notes on Books

The Central Council for Health Education (Tavistock House, Tavistock Square, W.C.1) has issued some new material. (1) *War on Disease*. This pamphlet outlines in simple language the ways by which various types of illness may be spread, and how to prevent this happening; it deals incidentally with the spread of venereal disease, in pursuance of the policy of letting education on this subject take its place naturally with that on other infections and contagions. (2) *Right Dress for Health*. A leaflet on clothing with particular reference to war workers and rationing difficulties. (3) *Nerves*. A leaflet giving hints on how to reduce nervous tension and "jumpiness." (4) *Measles*. The continued high incidence of measles has prompted this new leaflet (Health Hints No. 14). (5) *Pasteurization of Milk*. The article by Prof. G. S. Wilson, published on Feb. 27, 1943, in these columns, was felt to be of such importance that it has been reprinted by the Central Council with our permission.

Dr. EDWARD STAUNTON WEST'S *Physical Chemistry for Students of Biochemistry and Medicine* comprises the scope of study provided for in the regular course of biochemistry at the Medical School of the University of Oregon. The fundamental principles of physical chemistry are the same for all their diverse applications, and while the discussion of them is here directed only to biological phenomena they are enunciated and described in the form which serves as a foundation for all other applications. The author has been at pains in preparing this book to help the student who has had no previous instruction, and is to be congratulated on the lucid form of presentation which he has achieved, which is explicit without being prolix. Amplification of the text is given liberally wherever it serves to enlarge the instruction. Thus it is shown that the theory of the Donnan equilibrium, which was founded originally on thermodynamics, could have been deduced independently and equally well from kinetic considerations. The book is further characterized by a liberality in illustration of the principles of physical chemistry for explanation of biological phenomena, and in this respect also it is educationally informative in the highest degree. The publishers are the Macmillan Company, and the price is 28s.

HOWARD T. KARSNER'S *Human Pathology* is a well-established American textbook, the sixth edition of which (J. B. Lippincott Company; 63s.) has been extensively revised, and reset with two columns of print to the page, which makes for easy readings. An unusual feature is the exceptionally long lists of references given to guide the student in further reading, some extending to several pages: a smaller selection might be more helpful, or some indication of which papers are the most important. The teaching throughout the book is clear and orthodox, and the illustrations, many of them new, are excellent.

Surgeon Rear-Admiral C. M. BEADNELL has produced another book of reference—*An Encyclopaedic Dictionary of Science and War* (London, C. A. Watts and Co.; 25s.). The volume contains a mass of data concerning the adaptation of science to warfare, but for the most part the latest and therefore the most interesting information will of necessity not be available until the end of the war. Those who expect to find, for instance, the most recent developments in aero-engines, tanks, and radio as adapted to war uses may feel disappointment. The dictionary, however, is otherwise comprehensive, and its value is increased by the inclusion of many tables. Incidentally the last column of figures in the table on page 30 needs correction for the next edition. This is a book of reference that will prove of service to many.

As there is good reason to believe that the majority of medical men and women are in favour of individualism and against bureaucratic control, some of them may like to know of a 6d. pamphlet published by the Individualist Bookshop Ltd., 154, Fleet Street, E.C.4. It is entitled *The New Authoritarianism in Education*, and the three contributors are Dr. L. P. Jacks on "Home Rule for

Education," Mr. Stanley Maxwell on "Freedom in Education," and Dr. John Murray, Principal of the University College of the South-West of England, Exeter, whose chapter is headed "On Copying the Nazis."

Under the title *Plan for Clean Air* the National Smoke Abatement Society has published an outline of the case for smoke prevention in the popular form of a "quiz" of twenty questions and answers. The pamphlet may be obtained direct from the Society at its temporary wartime address, 94, Manor Green Road, Epsom, Surrey, single copies 2d. each, post free.

Preparations and Appliances

A DIATHERMY AND SUCTION HOLDER

Dr. RALPH FRIEDMAN writes from the West End Hospital for Nervous Diseases, Regent's Park:

Those who have to use a diathermy knife and suction apparatus have often been annoyed, or possibly angry, when at the critical moment neither was to be found at hand. Inadvertently they have fallen from their precarious positions on to the floor and have become unsterile, precious minutes thus being lost in substituting new sterile appliances.

After much thought I have devised a very simple and inexpensive instrument which would end the unnecessary headaches that bothered us and help our brain operations to proceed smoothly and harmoniously. The apparatus, as can be seen

FIG. 1

FIG. 2

(The above photographs were taken by Mr. Jean Straker)

from the two photographs reproduced here, is clipped on to the sterile sheet; the diathermy and glass sucker fit neatly into a spring clip at either end.

My chief and I have tried this dual instrument-holding clip and have found it most useful and satisfactory. Whenever the diathermy knife or suction apparatus was wanted it was exactly where we had placed it. I have named this instrument Mr. G. C. Knight's diathermy and suction holder as a token of respect and esteem to my neurosurgical chief. I hope that others too will find the same satisfaction in using it.

Messrs. Down Bros. have been most helpful and have done their best to make the instrument as rust-proof as it is possible.

MEDICINE IN TRANSITION

At this moment the medical profession is at a critical turning-point in its long history. The war and the Beveridge report have quickened the evolutionary change through which the practice of medicine is going, and in the view of some at such a speed as to threaten us with a revolution in our professional affairs. The remarkable developments in medical knowledge and technique during the past two or three decades and the growth of the social services have both gone to mould the new ideas in the world of medicine on the form and content of the health services. As more social services are supplied, so are more demanded, and demanded as a right. The medical services—or, as it has become fashionable to call them, the health services—are essential to the nation's life; and that they should be available to everyone without fear or favour is undeniable. But just as the public has a right to demand that these services should be at its disposal, so should it recognize its obligations to those who give the services and also take into account the demands of the medical profession. Many publicists these days talk and write as if the public, being the paymaster, must have the loudest, and indeed the only, voice in deciding what health services should be rendered, and how. The medical profession is justly proud of its tradition, and of the service it has rendered to this country. While, therefore, it must take full account of the actual position of medicine in the world of to-day, it needs to be conscious of its strength and position if it is to meet tomorrow the sudden introduction of changes which the bulk of doctors may regard as inimical to the practice of the art of medicine.

We were told earlier this year in a published letter from the Secretary of the Ministry of Health that the Government's projected scheme "will of necessity affect deeply the structure of the medical profession." We were told also in the same letter that at some stage a statement would be published, "indicating in general terms the kind of measures which the Minister would have in mind to submit to Parliament on behalf of the Government." "This," it was added, "will afford your group ample opportunity for further deliberation and reference back to the constituent bodies; and in framing any time-table we shall not lose sight of the fact that so many of the profession are serving over-seas." This statement is now awaited in the form of a White Paper, expected to appear within the next six weeks. That it shall be couched "in general terms" and not embody any cut-and-dried plan has been urged upon the Government by the Representative Committee. That, in fact, the Ministry of Health has considered specific plans became clear in May, and doctors in this country caught a glimpse of how deeply the proposed changes—if they became actual—would affect the structure of the medical profession.

The course of events is clearly outlined in an address in this week's *Supplement* by Dr. G. C. Anderson, the Secretary of the B.M.A., who from his great experience puts forward the Association's general policy and argues that the changes which it has long advocated would go far to implement Assumption B of the Beveridge plan. We endorse his view that the White Paper should not be prejudged, and that when it does appear it should be sub-

mitted to calm, dispassionate examination and criticism. The man who loses his temper in an argument usually gets the worst of it, and it is evident that in subsequent negotiations with the Ministry of Health any professional negotiating body will have to be very clear-headed. At the same time, if the medical profession is to be asked to give up its freedom of individual action through conversion into a whole-time State salaried service, emotion cannot be kept out of the argument. No man can view the surrender of personal liberty with dispassion. We suggest, therefore, that the emotions that may be aroused should not be wasted on side-issues, but should be controlled and used as a driving force behind the reasoned argument that our negotiating body will place before the Government's representatives. There is, indeed, one emotional attitude prevalent at the moment that should be dissipated—an attitude of defeatism represented by the statement, "A whole-time State salaried medical service is inevitable, therefore why resist?"

In about two weeks from now the Representative Body will have placed before it certain general principles agreed upon by the Council at its meeting in July.¹ We would draw attention here to Recommendation K—on the need for reform of central and local health administration. As Dr. Anderson with proper emphasis states: "We must insist that until the administrative foundation is clearly laid no other changes will be initiated"; and again, "One thing we are all agreed on is that we shall not accept a medical service which is administered by local authorities in their present form." In the reformed central and local administration there must be statutory medical advisory committees to be consulted on all matters of major health policy. In the next two weeks representatives, therefore, may well give close attention to the present administrative structure of central and local health government, so that they may be clear about the reforms they must insist upon before any kind of new medical service is even contemplated. The present framework is unacceptable to the medical profession. But whatever the framework, and whatever kind of service is fitted in it, what will determine the quality of the medical services in this country will be, as always, the quality of intellect and character of the individual doctor in that service. This in turn will depend upon the interaction between the natural equipment of medical students and the kind of education they receive. This education, so far, has been given by the voluntary teaching hospitals of this country and the schools associated with them. If the character of these hospitals is changed, then it is not impossible that the character of medical men will change too. This is not to say that medical education does not need revision, and repeated revision. The training of the medical student and the provision of facilities for medical research are more important to the health of this country than any one of a multitude of plans.

Until the Ministry of Health and the local authorities have reformed themselves, before starting to try to reform the medical profession, there will be little likelihood of administrative progress. In the meanwhile the Council of the B.M.A. proposes that the National Health Insurance Scheme should be extended to include dependants of insured persons and others of like economic status, and to cover consultant and specialist services and laboratory and hospital facilities. One of the real medical needs of this country is a clinical pathological service such as is afforded now by the Emergency Public Health Laboratory Service. In the absence in peacetime of such provision the practising doctor was working with one hand tied behind his back. The other immediate step recommended

¹ See *Supplement to the British Medical Journal*, Aug. 7, 1943.

s to experiment in group practice. Here, clearly, prolonged esting must be undertaken. But what is needed above all else is to bring the general practitioner back to his full status as a responsible clinician, having the complete care of the individual health of the members of the families who seek his advice. The rate of change of medical science suggests that the general practitioner of the future will do his work better in closer co-operation with professional colleagues, but whether in a health centre or not remains to be decided.

Changes are bound to come, and indeed have been urged for years past by the B.M.A. The direction these changes will take is as much the concern of the medical profession as of the public, and a harmonious agreement will be reached only if both take into full account the obligations and the rights of each other: to insist on all right on one side and all obligation on the other will lead to an impasse. A broad and sober outlook is now required of the profession, and Dr. Anderson's address gives a statesmanlike lead. His exposition is so clear, and it will be read so widely, that no embroidery here can be needed.

Rh IN PROGNOSIS AND TREATMENT OF HAEMOLYTIC DISEASE OF THE NEWBORN

It can hardly be doubted that Levine and his collaborators are right in stating that iso-immunization of the mother plays an important part in the causation of erythroblastosis foetalis, more properly called haemolytic disease of the newborn. Levine says the disease results from the mother making or having an antibody to a foetal red-blood-cell antigen, inherited from the father but lacking in the mother herself, and the subsequent passage of this antibody through the placenta to act on the child's susceptible blood. The Rh factor is the antigen most commonly involved. Tested with human sera containing anti-Rh agglutinins, the red cells of 85% of people in this country are found to contain Rh (Rh-positive); 15% (Rh-negative) lack it. Hoare, whose results are recorded elsewhere in this issue, has found the same frequencies, testing with the sera of guinea-pigs injected with the red cells of the rhesus monkey; similar results have been reported for the white people in the U.S.A. In one pregnancy in ten the mother is Rh-negative and the foetus Rh-positive; and in one in five the mother has in her serum an agglutinin for an antigen of the A-B-O groups present in her foetus. Haemolytic disease seems to occur once in about 400 pregnancies: that is, in only a few where the blood groups make it possible, so other factors not yet understood must be concerned. Race, Taylor, Cappell, and McFarlane, in an article at p. 289, record their investigations of 50 families in which the disease was diagnosed, and have confirmed previous findings that about 90% of mothers of erythroblastic babies are Rh-negative and that anti-Rh agglutinins occur in the sera of most of these mothers, sometimes years after the last pregnancy—a fact of importance in blood transfusion. Where the mother is Rh-positive it seems that another antigen must be responsible, such as those of the A-B-O groups and subgroups, and the M, N, and P factors. Even when a mother is Rh-positive it is not certain that trouble due to Rh will not arise: she may make a sort of anti-Rh which acts on the red cells of all Rh-negative and of many Rh-positive persons, including her child's. This unusual type of agglutinin, because it works, as it were, the other way round from anti-Rh, has been called anti-Hr; it appears to be an antibody to the Rh-negative factor, which, like the O of the A-B-O groups, must be more than merely an absence of Rh. Some workers have noted a surprisingly high proportion of Rh-negative men among the husbands

of Rh-positive mothers of affected children, and it may be that many cases with Rh-positive mothers are due to anti-Hr; but to produce anti-Hr the father need not necessarily be Rh-negative; it has arisen when both father and foetus were Rh-positive.

A question asked with increasing frequency at the present time concerns the chances of an unaffected child being borne by an Rh-negative mother who has had an affected child or children. If the Rh-positive husband is homozygous (RhRh) all subsequent children will be almost certainly affected, for they will be Rh-positive; if he is heterozygous (RhRh) each child will have an even chance of being Rh-negative and of escaping the disease. But in such families there appears to be a marked scarcity of negative children, due to the majority of the fathers being homozygous. The mother is much more likely to be immunized when every pregnancy produces the antigenic stimulus, as it does with a homozygous husband, than when he is heterozygous and some children are positive and others negative. If the father has declared himself heterozygous by producing an Rh-negative child, the chance of the next child being negative and unaffected is one in two; but in the absence of this indication the prognosis is unfavourable.

Although knowledge of the part played by the Rh factor leads to a gloomy view of the chances of a normal child being born in a family in which the disease due to Rh has occurred in an earlier pregnancy, it has suggested a line of treatment which has given very good results in children who have lived long enough to receive it. In the past, attempts to replace by transfusion the blood destroyed by lysis have not been very successful. The lysis is due to the child's Rh-positive blood cells reacting with the antibody made by its Rh-negative mother, and as six out of seven donors are Rh-positive and untested blood was used, mostly positive blood was given, and this, like the child's own, was liable to be destroyed. As soon as erythroblastosis foetalis is diagnosed—and where there is a previous history cord blood should be examined—the child should be transfused with O Rh-negative blood, injected into the veins, not into the muscles. The mother's whole blood, although Rh-negative, should not be used, as the plasma will almost certainly contain the harmful antibody. If no other negative blood is available, and the A-B-O groups permit, the mother's cells washed free from plasma may be given. If Rh-negative blood is not available from any source blood from an O donor taken at random may be used, but it will usually be Rh-positive and may cause a transient jaundice. The father should not be the donor, and Rh-negative blood is more likely to be found among the wife's than among the husband's relatives.

The practical application of this work is exemplified by Janet Gimson's article at p. 293, in which she describes a series of 18 affected babies treated by transfusion with Rh-negative blood. All the babies were Rh-positive and their mothers negative, and in the sera of all but one of the mothers anti-Rh was found. Whilst all the infants received Rh-negative blood, some of the earlier cases were given Rh-positive blood as well; but, although with Rh-positive blood there was an initial rise in haemoglobin and red cells, haemolysis continued, and within a few days further transfusion was needed. Rh-negative blood does not prevent haemolysis of the child's own cells: it merely provides cells which will not be destroyed more rapidly than normal and on which the child may live until the haemolytic process ends. When a mixture of Rh-positive and Rh-negative blood was given the negative cells survived normally while the positive were often destroyed within a few days. In 14 of the 18 cases given Rh-negative blood the results are described as "perfect"; the other four regained and main-

tained normal blood pictures. No more than two transfusions of negative blood were needed in any case. How encouraging are the results of the treatment given to these 18 babies is seen when they are compared with a series of 17 consecutive infants treated at the same hospital by transfusion of blood which would nearly always be Rh-positive, as it was not examined for the factor. Six of the 17 died from the disease or transfusion; four were kept alive but without any improvement in the blood condition; and only seven did satisfactorily, although much more blood was given to them—up to six transfusions to some—than to the 18 cases treated so satisfactorily with Rh-negative blood. Moreover, no reactions followed transfusion of Rh-negative blood, but in the other series, where untyped blood was given, more often than not there was a rise of temperature and some constitutional disturbance with increase of jaundice and size of liver and spleen. On admission to hospital the ages of the 18 babies varied between three days and six weeks, and, although it is well known that some cases even of icterus gravis will recover without treatment, the mortality is very high. There can be little doubt that treatment with Rh-negative blood is full of promise, and if a child lives long enough to receive it there is an excellent chance of its survival. Gimson thinks there is little hope of transfusion influencing kernicterus—the suggested incidence is 10% of affected children—with the dreaded mental and other conditions which may possibly follow it.

MEASLES VACCINE

Passive immunization with convalescent serum, adult serum, and placental globulins is not entirely satisfactory in the control of measles, and there is need for a virus vaccine which will confer a solid and lasting active immunity in interepidemic periods. One difficulty in the research work on the virus of measles has been the lack of a convenient laboratory animal susceptible to the disease. Although several Japanese workers have claimed transmission to guinea-pigs and rabbits by testicular passage, Mayer¹ could not confirm their results, and suggested that activation of latent virus III infection had led to false interpretation. The monkey *Macaca mulatta* is susceptible, but obviously cannot be used in large numbers. Monkeys have been infected with blood and filtrates of nasopharyngeal secretion collected in the pre-eruptive and early eruptive stages of infection. The incubation period is the same in the monkey as in the susceptible child, and signs and symptoms are also similar in both, although somewhat milder in the monkey. After the animal recovers from a mild infection it is immune to a second attack.

Stokes and his collaborators² have recently made a careful preliminary study of a virus vaccine attenuated through repeated passage on the chorio-allantoic membrane of the developing hen's egg. The living virus was then either kept frozen or desiccated from the frozen state, and, where possible, tested for infectivity in the monkey. Two hundred and fifty-five children, most of whom had reliable medical histories which excluded previous measles, were vaccinated in various institutions in New Jersey and Philadelphia, and there were 37 unvaccinated controls who were exposed to the inoculated children. Inoculation was by inhalation or by the intranasal, subcutaneous, or intradermal route. An attenuated disease was produced in the great majority of vaccinated children, signs and symptoms including Koplik's spots, exanthem, conjunctivitis, coryza, and fever, but there was only mild malaise and almost complete absence of cough. The fever was not sustained, and the children were "brighter, more active, and far less toxic than is usual in

measles." The reactions described, however, were far from negligible and would prejudice any scheme of mass immunization. The disease in the 37 unvaccinated "contact controls" differed in no respect from that observed in inoculated; there was thus no evidence that one passage of the attenuated virus from one human being to another produced any increase in virulence. The authors realize that in planning further research there are many factors still to be assessed, including the selection of virus strain, the potency and dosage of the virus inoculum, and the method of inoculation. Before a method can be generally applied it must be shown to be safe; the use of modified living virus in the control of certain other diseases has proved not to be devoid of risk. In a second report³ the same workers state that 22 vaccinated children were exposed to chance infection in an epidemic, and 7 developed the disease (3 attacks typical, 1 mild, 3 extremely mild). As a control to this group 7 vaccinated children in one school were intimately exposed to infection; none contracted measles, compared with 25 cases of measles among 36 susceptible children. Of 24 vaccinated children who received challenging injections of blood from active cases of measles during the early stages of the disease, developed measles (3 typical attacks, 2 mild, 5 extremely mild, 1 "slight nasopharyngitis" without other symptoms). Six suitable control children received injections of the challenge material and all six developed typical measles. In short, 40 of 46 vaccinated children appeared to have considerable protection against measles—results sufficiently encouraging to demand further clinical trial.

A reliable serological method for the estimation of antibody is urgently needed. While no such method is yet available, the developing chick embryo appears to provide a source of antigen in sufficiently high concentration. Results are awaited of further laboratory investigations carried out possibly in conjunction with clinical trials of virus vaccine.

MEDICAL CARE OF SCHOOL CHILDREN

The Government's proposals for educational reconstruction, so far as the medical inspection and treatment of school children are concerned, are obviously limited by the uncertainty about the place, if any, of the school medical service in the health services of the future. The White Paper (Cmd. 6458, price 6d.) which has been presented to Parliament by the President of the Board of Education, does, however, contemplate that when a "comprehensive national health service" is in operation "it will no longer be necessary for local education authorities to provide medical inspection and seeing that children and parents are properly advised and encouraged to seek treatment through the new health channels any treatment the children need." This is good so far as it goes; it is to be hoped that the "new health channels" will be the family doctor, as is the work of the school clinic, it does stand in the same relationship to the child and the community as does the family doctor, who knows the family's history and environment, and who, more often than not, has brought the child into the world. In the meantime it is to be a duty of education authorities to see that all children at grant-aided schools who need treatment (except domiciliary treatment) receive it; and no action is to be made for this. Hitherto the obligation of education authorities as regards treatment extended only to children in a public elementary school, and the requirement by statute to recover the cost, except where it was manifestly unreasonable to do so. It will also be a duty of education authorities in future to provide

¹ Arch. Hyg. Bakt., 1941, 126, 285.
² J. Pediatr., 1943, 22, 1.

meals and milk; previously they had power to do so only where the child through insufficient feeding would not profit from its education. The school meals service and the milk-in-schools scheme have already been greatly expanded since food rationing began, but the new duties laid on education authorities will mean still further extension of both these services.

Part-time education is to be compulsory for all adolescents between the ages of 15 and 18 who are not already attending full-time at school or otherwise under suitable part-time instruction. The curriculum will include physical training and instruction in health and hygiene, and the medical care of these persons will be provided by the school medical service. Finally, it is to be a duty of education authorities—not merely a power as hitherto—to establish nursery schools for children under 5 wherever the Board of Education thinks them necessary. These are especially needed, the White Paper states, in the poorer parts of large cities. Medical opinion, if one may judge from the discussion at a recent meeting of the London Association of the Medical Women's Federation (*Journal*, July 17, 1942, p. 84), does not favour the communal nursery for children under 2, nor the provision of nurseries for those from 2 to 5 as part of our educational system. Some training and instruction of the mother at a communal centre, like the Peckham Health Centre, to which the nurseries could be attached would, it is held, more suitably provide for the health and well-being of the "under fives."

HYPERTENSION AND HEIGHT

The work of Kretschmer and of Draper has put many a clinical observer on to the fascinating trail of correlating disease conditions with physical types. It has, for example, been stated that high blood pressure is most common among short persons, but statistical inquiry has failed to establish any clear association between height and hypertension. This question has been examined again by Robinson,¹ who gives data relating to 7,478 adult males and 3,405 adult females. Taking the two groups together, the short men and short women have very slightly higher systolic pressures than the tall groups, which is in agreement with the general findings. The author proceeded to classify the heights into three arbitrary groups: short, medium, and tall. The short men were under 66 inches and the tall men 71 inches and over; the short women were less than 63 inches and the tall women 66 inches and over. Each of these groups were further subdivided according to build into slender, intermediate, and broad. The criterion of a slender build was that the chest/height ratio was less than 0.5, and for a broad build it was 0.59 and over. Among the men within each of the three build groups there was only slight variation in the mean systolic and mean diastolic pressures between the three height groups. But there were larger, though insignificant, differences among the women. A considerable rise in both systolic and diastolic blood pressures was shown within each height category as body build progressed from slender to broad, this increase being greater for females than for males. The difference in the mean systolic pressure of the slender and broad build groups was 13.7 for short men and 13.8 for tall men, and for the corresponding female groups it was 18.3 and 24.9; for diastolic pressure the differences were for short men 9.1, tall men 10.4, short women 9.1, tall women 17.6.

Robinson compared the incidence of low and high systolic and diastolic pressures among the short and tall men

and women. Low pressure was taken as under 110 mm. for systolic and under 70 mm. for diastolic, with high pressures 140 and over and 90 and over. He found that for both male and female the tall groups had a greater incidence of hypertension, both systolic and diastolic, than the group of short stature, and less low pressure. This was most marked in the broad build groups: 16% of the short broad men and 13% of the tall broad men had low systolic and diastolic pressures. Systolic hypertension occurred in 18% of the short broad men and 29% of the tall broad men, and diastolic hypertension in 16% of the short broad men compared with 23% among the tall broad men. The explanation of this finding, which is apparently a contradiction of the results from all observations combined, is that there are many more short broad persons than tall broad persons in the general population, and, although the tall broad person is more susceptible to hypertension than the short broad person, this increased susceptibility is more than offset by the greater number of short broad persons. Hence all short men together will show a higher mean pressure than all tall men.

The author concludes that the tall person has a greater risk of hypertension than any other individual, and that the difference in blood pressure between tall and short persons in specific build groups is due solely to a height difference.

THE RESEARCH DEFENCE SOCIETY

While the six anti-vivisection societies reported an income of over £50,000 in the last pre-war year (a sum probably much exceeded by now, especially in view of some recent legacies), the Research Defence Society manages to be alive and to "kick" with some vigour on a modest income of only about £500. No doubt if the R.D.S. adopted popular and pictorial (and one might add misleading) methods of propaganda, its support would be multiplied, though a body which makes a sober scientific appeal can hardly ever hope to rival another which makes a highly coloured sentimental one. Nevertheless, on an income of about £10 a week the R.D.S., as its latest annual report proves, manages to carry on a great deal of excellent work. Its principal concern during the past year has been to combat the anti-inoculationists in the field of diphtheria and of small-pox. Sir Leonard Rogers, whose pen is unwearied in the Society's behalf, has assembled in a paper the information up to date concerning the results of preventive immunization against diphtheria, with some telling facts and figures, especially in relation to the recent campaign in Scotland, and this has found a wide distribution among local councillors and members of health committees, where it should prove most serviceable. The fatal outbreaks of the virulent Indian type of small-pox, following the arrival of a ship at Glasgow in the summer of 1942, afforded the R.D.S. another opportunity to point the moral. After the vaccination of known contacts had failed to stop the occurrence of cases, mass vaccination was carried out in each of the infected areas, and the calamity of a widespread epidemic was averted. Sir Leonard Rogers took advantage of the occasion to publish a paper, in the form of an address to a ratepayers' association, on the efficacy of vaccination against smallpox, and this also has been circulated in quarters where such enlightenment is most needed.

We much regret to announce the sudden death of Sir Francis Fremantle, M.P. for the St. Albans Division since 1919, chairman of the Parliamentary Medical Committee since 1923, and a past-president of the Society of Medical Officers of Health.

THE EDUCATIONAL BACKGROUND FOR THE PROFESSION OF MEDICINE*

BY

A. E. CLARK-KENNEDY, M.D., F.R.C.P.

Physician to the London Hospital and Dean of the Medical School

The rapid advance of medical knowledge in recent years which has made such great contributions to the prevention of disease and the relief of human suffering has, at the same time, had two inevitable and rather unfortunate consequences. On the one hand, it has resulted in an increasing degree of specialization in medical practice. On the other, it has enormously increased the requirements of medical education. The former is undermining the position of the general practitioner in the country. The latter has resulted in technical education in the universities and schools, and the general education of many medical students is now an altogether inadequate background for their future position in the community. Let me therefore give you a brief account of medical practice in order that we may see the attributes of character which the profession of medicine demands and that you may form some opinion of the educational requirements of future medical practitioners. Then, being myself uneducated in the classics, I must leave it largely to you to decide for yourselves whether these requirements can or cannot be met by a classical education.

Empiricism in Medical Practice

The general public usually have a misconception of the real nature of medical practice. Medicine deals with human life, and they forget that life of every kind from the scientific point of view still remains completely unexplained and utterly mysterious. We have advanced a long way recently, particularly in the prevention of epidemic disease, in our knowledge of dietetics, in our surgical technique, in the use of drugs, but most, if not all, of our knowledge, in view of our complete ignorance of the nature of life, is still really empirical. The doctor cannot limit his work to forces under his control. He is compelled to use physical and chemical agents in the treatment of diseases of a body which as yet we understand but little and in disorders of the human mind which so far we comprehend still less. We really know very little about medicine. The general practitioner, however, struggling with one insoluble problem after another, is faced with practical situations and is expected to produce results. Most patients demand miracles. Nature may work the miracle, or science succeed when Nature fails, but he is confronted repeatedly with slowly progressive conditions of unknown origin for which there is no certain treatment. These patients demand cures, and again and again he finds himself in an almost impossible position.

In addition the general practitioner has to contend with the defects of human character and the peculiarities of the human mind; with patients in whom fear upsets the working of the body and with people who use ill-health to escape the responsibilities of life. Many of his patients are children, and children constitute a problem in themselves. He lives in the society which constitutes his practice, and is compelled to compete with his fellow practitioners to earn his living. The practitioner must keep up to date with a rapidly advancing subject. He is, or should be, guide, philosopher, and friend to all sorts and conditions of men, and among rich and poor he must be prepared for all degrees of intelligence, every variety of religious belief, any moral standard. When young he has to deal with older men, and must imagine for himself what it is like to be old. When getting on in years himself, if he would be successful with his younger patients, he must recollect the point of view of youth. Lastly, he has to deal with incurable and dying people. He must know how to handle death: when to cease to "strive officiously to keep alive." What a life! I am not saying that general practice is always well done, but in this country we are still fortunate in the high standard of general practice, far the most difficult and in a way much the most important branch of the profession. Anything which

undermines the position of the general practitioner will be a disservice to the whole community.

Attributes of the Doctor

What, then, are the attributes of character required for profession of medicine? First, common sense, wisdom, sound judgment, which are always so much required on borderline of scientific knowledge. Then an equal interest in science and the humanities; a capability for sympathy with the misfortunes of man, imagination so as to visualize processes going on inside the body, and human understanding to perceive the thoughts passing through the mind; lack of prejudice; intellectual honesty and a capacity for criticism in relation to alleged discoveries and new methods; a sense of values and a philosophical attitude towards life and death; the personal character to command respect and maintain discipline; an interest in the organization of society, a reasonable degree of manual dexterity, and a capacity for accurate observation.

This is demanding a great deal; and how, then, do we select for the medical profession? In the first instance on the school certificate! After this, general education for the boy or girl who wishes to take up medicine usually ceases altogether, or is continued in a half-hearted kind of way, because, unfortunately, an examination in chemistry, physics, and biology now remains the only requirement for the next rung of the ladder of medical education! Not only is general education therefore neglected but this has created the unfortunate impression that a school aptitude for these subjects is the main indication of the quality required for the profession. Of course we want some boys with these tastes, but too many with tastes exclusively of this kind wish to become doctors. The universities endeavour to exercise a judicious selection on grounds of personality, character, educational background. But the main problem is how to encourage more of those boys and girls with wider interests to take up medicine, and, after they have started, how to see that for all medical students their professional training does not crowd all other education out of the curriculum.

A Classical Short Cut

In the first place, the universities must reconsider their policy and see that their examination systems do not necessitate specialization in science at school and that some opportunity is afforded at the university for medical students to continue their general education. In the second place, the schools must encourage boys with personality, character, and human interest to take up medicine, as well as those with an exclusive interest in the admitted beauty of modern science or an understanding and fascination for laboratory technique. The boy who decides to take up medicine, however great his interest in laboratory work may be, must realize from the start that medicine is merely an affair of science. The humanities do matter. There must be taught that a study of literature can be made a short cut to that understanding of human beings which will require so much in general practice, and that modern languages will also provide him in adult life with access to the wider field of the medical and general literature of other countries. He must learn to think in terms of scientific progress and social evolution. He must be made interested in the general outline of history, and taught to see how the main streams of human thought have converged to produce our present outlook. His education must not be exclusively classical, but all that is surely quite impossible without some knowledge of Greece and Rome. Moreover, the classics should be able, if properly taught, to provide in a peculiar way that cultural background which the medical student should have for his technical education and which the average doctor requires for his professional life.

The Greeks were particularly interested, as the doctor is, in man. They puzzled over the meaning of life and tried to interpret the tragedies of human existence in which the doctor becomes so familiar. They struggled with the moral law, and in all their inquiries maintained that balance between the study of things and an interest in people which is so important in medical practice. Hippocrates started accurate observation of disease, and Plato foreshadowed the modern attempt at the understanding of the mind. The Greeks

* A contribution to a symposium on the value of the classics in education for various walks of life at a meeting of the Classical Association in Cambridge.

act, struggled with the same political, moral, medical, and social questions as we face to-day, and the history and thought of Greece epitomize all the problems of the twentieth century. A study of the classics is therefore a short cut to that knowledge of human life which is so essential in a young doctor when starting in medical practice.

History before Syntax

But can this aspect of the classics really be "put across" to the adolescent mind at school? I ask for information. Are the classics at present really taught with this intent, or is he object of teaching classics mainly to encourage accuracy and inculcate mental discipline? If so, science and mathematics can do this just as well. Or are the classics taught from the point of view of the structure of language, or merely to provide the technical basis for a real but rather improbable classical education at the university? I doubt, personally, if it is possible to teach the classics at school as a background for medicine in the original dead languages. If a classical education is to provide the background that medicine requires (which I believe it can), and if boys so educated are to be stimulated to take up medicine (which is what we want), then boys must be taught less Greek and more about the Greeks. Translations of the classics must not be despised. Greece and Rome must be brought into relation with the modern world. A study of the past must be made a stimulus and guide both to the handling of the present and to the planning of that post-war world in which medical men will be called upon to play such a particularly important part.

A real appreciation of Greek medicine only comes with experience. But let us never forget that Hippocrates set for all doctors and for all time the ethical standard of medical practice:

"I swear by Apollo, Physician, by Asclepius, and by all the Gods, to hold my teacher in this Art equal to my own parents, to teach his family this Art, if they want to learn it, without a fee: . . . I will use my treatment to help the sick according to my ability and judgment: . . . I will not administer poison or procure abortion: . . . I will keep pure and holy my life and my Art: . . . I will not use the knife, but give place to such as are craftsmen therein: . . . and whatsoever I shall see or hear in the course of my profession I will never divulge, holding such things to be holy secrets."[†]

In education translations of the classics are, in my opinion, of some value!

THE COMPRESSED CURRICULUM

ARRANGEMENTS FOR NEW SESSION AT MEDICAL SCHOOLS

It will be recalled that early last year the Minister of Health, in view of the demand for medical man-power, brought to the notice of the General Medical Council a recommendation from the Medical Personnel (Priority) Committee in favour of some curtailment of medical study. The modification suggested by the Priority Committee was that students who produced evidence of having completed the whole of the curriculum after not less than 30 months of certified clinical studies should be admitted to the qualifying examinations. The General Medical Council was satisfied that under war conditions no objection should be taken to a departure to this extent by licensing bodies and examining boards, but it instituted an inspection of examinations where this proposal had been adopted.

Of the 22 licensing bodies in the United Kingdom 19 have adopted the recommendation of the Priority Committee; the other three had taken anticipatory action which had the same effect of accelerating admission of students to the qualifying examinations.

The Schools in London

The various medical schools seem to have adjusted themselves without any formidable difficulty to the new requirement whereby 36 or 32 months of study are compressed into 30. The Dean of the London Hospital Medical College states that the shortening of the Conjoint curriculum by three months has had no appreciable effect on the organization of the

teaching, and the Dean of St. Bartholomew's says that it has proved quite possible to fit the courses hitherto taken into a period of 30 months. From St. Thomas's Hospital comes the remark: "While we necessarily accept the ruling [condensing the clinical curriculum into 30 months] we look forward to the time when this unfortunate cut will be again readjusted." The Dean of St. George's Hospital Medical School states that there has been little or no shortening of the various courses, but that as students take only very short holidays nowadays they find it possible to meet the requirements of the examining bodies in a shorter time than in the pre-war era. At University College Hospital the course has been compressed in one or two respects so that students may—and for the most part do—enter for the finals after completing 30 months of clinical study. The London (Royal Free Hospital) School of Medicine for Women has found that the reduction to 30 months necessitates a certain amount of dovetailing of clinical work, but no changes have been made in the details of the course. That seems to be the position, more or less, in all the London schools. The Dean of one of them writes: "My college is just as it was, without any alarming or extensive reconstruction, and is doing very well, thank you."

Provincial Schools

At Manchester clinical teaching is to begin only in April and October of each year, when an introductory six-months course will be given. The curriculum here has been revised in order to leave the sixth year free from university classes, to enable students to concentrate on hospital work, and to give them a chance to hold resident appointments with a view to accelerating qualification and accustoming them to a certain amount of responsibility. Systematic teaching in pathology is to begin immediately after the examination in anatomy and physiology. The teaching of pharmacology is to include anaesthetics and therapeutics, and the course is to run concurrently for five terms with that of pathology and bacteriology, examination in all three subjects—that is, pharmacology, pathology, and bacteriology—to be taken at the same time.

Durham students, at the medical school at Newcastle-upon-Tyne, are being allowed to sit for their final examinations six months before the normal date. Certain courses and examinations are therefore being expedited; otherwise there is no special alteration in the curriculum as a whole. At Birmingham the curriculum has been shortened by six months, thereby giving students the option of taking their final examinations in December instead of the following June.

Until the present session no curtailment of the curriculum had been made at Sheffield, as it was felt that the standard of medical education should be maintained if possible, and that in a small school the number of students qualifying each year is so insignificant that the speeding up of the date of qualification would not assist the national effort to any material extent. But now, to conform with the practice generally adopted by the medical schools, a revised time-table for fifth- and sixth-year students has been drawn up under which the students due to qualify in March, 1944, will do so in December, 1943. Next year those who would have qualified in the ordinary way in March, 1945, will do so six months earlier. The first gain of three months has been made possible by telescoping the lectures of the last half-year of the usual course and by depriving the students of the final three-months revision period. The eventual gain of six months is brought about by the introduction of a summer vacation term for fifth-year students, beginning only a few weeks after the completion of their fourth-year course, and by curtailing the final medical and surgical clinical appointments and the final revision period.

Leeds, in complying with the request to reduce the clinical period to 30 months, made the reduction applicable to the group of students who are due to complete their final examination in March next, thus allowing successful candidates to take their degrees this September. The Dean states that it has not been easy to compress the last 18 months of the curriculum into 12, but the compression has been spread as evenly as possible over the whole of the clinical period, and thus the strain on the student has been lessened. But he mentions also the heavy strain on the teaching staffs caused by the exigencies

[†] Leeb's Classical Library. *Hippocrates*, Vol. I, p. 299. Translated by W. H. S. Jones. William Heinemann, 1923.

of war—a strain which the shortening of the clinical period has done nothing to ease.

The final part of the curriculum at Bristol has been compressed to enable those students who would normally qualify in June, 1944, to take their final examination in December, 1943, if they wish to do so. A similar arrangement at Bristol last year enabled a small number of students, who would normally have qualified in December next, to take their final examination last June. The Welsh National School of Medicine at Cardiff has also shortened the clinical period to 30 months while making every endeavour to maintain quality and content. A third degree examination is now held each year in addition to the usual two.

Arrangements at Oxford and Cambridge

Special arrangements at Oxford and Cambridge have resulted in considerable saving of time. At Oxford most of the students, having taken physics, chemistry, and biology before coming to the university, begin work on anatomy and physiology during their first university year. At the end of their first term they are able to take organic chemistry, and thereafter to prepare for the examinations in human anatomy and physiology for the first B.M.; these they take in their sixth term. Hitherto, in peacetime, they have obtained their B.A. degree (without which they cannot take the B.M., B.Ch.) by specializing for a year in work for the Final Honour School of Animal Physiology, but during the war a pass B.A. degree is being awarded on the results of the first B.M., and the Honours examination is taken only by specially recommended candidates. After passing the first B.M., usually at the end of the second year, the student immediately begins to prepare for the second B.M., with examinations in seven subjects, the last three of which—medicine, surgery, and midwifery—must be passed simultaneously. These are now taken in the fourteenth term from university matriculation instead of the eighteenth term as in peacetime, thanks to the saving of the year aforesaid.

Another wartime departure at Oxford is that whereas, after passing the first B.M., the students continued their training at one of the London or Provincial teaching hospitals, they now, to the number of about fifty a year, are given the opportunity of taking the whole medical course at Oxford. The advantages of this, in the particular field of ophthalmology, were mentioned in an annotation in the *Journal* of July 31 (p. 144). The standing committee allows hospital practice of less than the peacetime 33 months wherever reasonable; most people do 30 months, but some less.

One of the bodies which anticipated the Government's requirements was Cambridge. When it was foreseen that the need for doctors would become acute as the war went on, changes were made which had the effect of reducing the compulsory period of pre-clinical study from three years to two years, and in consequence of reducing the total period of medical study from six years to five. As a result there went down from Cambridge in the autumn of 1939 very nearly double the usual number of medical students, for in addition to the men who had completed the normal period of three years' pre-clinical study, a large number of students at the end of their second year were able to pass examinations in anatomy and physiology in October and to begin clinical work. The long result of this action matured in 1942, at just about the time when the Army increased its demands for medical practitioners, and during that year approximately double the number of candidates sat for the final examinations. This figure, of course, will be only temporary, and the number of candidates who present themselves for the final examination in this and subsequent years will not exceed the normal.

One other war change at Cambridge has been the putting in abeyance of the regulation which requires medical students to read for honours. In times of peace students have to reside in Cambridge for three years and to obtain an honours standard in a tripos. Almost all Cambridge medical students have taken the Natural Sciences Tripos, and it is probably true to say that the courses of instruction for this tripos constitute the greatest contribution which the university makes to medical education. But while this regulation has been put in abeyance it has been a source of great satisfaction that a large number of men have voluntarily taken the tripos courses and many

have succeeded in reaching a good standard in Part I of Natural Sciences Tripos at the end of their second year.

The Scottish Schools

At Edinburgh there has been no general shortening of five-years period of study which normally has to be at the university, but in order to release a number of 1 year students for hospital work and service in the Fore early as possible a group of 30 selected students have their course expedited so that they may qualify six months earlier than the normal date. This plan was introduced in 1942 and has been continued this year. It is brought about by utilizing the summer vacation for regular teaching number of final-year subjects.

To accelerate the qualification of students at Glasgow final professional examinations for the session 1943-4 have advanced by three months and will be held in December June next, when the clinical examination for the degree M.D. will also be held. At Aberdeen there has been shortening of the curriculum for the M.B., B.Ch. St before the war it was decided to lengthen the curriculum five years to five years and two terms—that is, 17 terms all—which would have meant, had this original proposal adhered to, that during the current year 1943 there would have been no medical graduates. To avoid this the university instituted a fourth term in the fourth and fifth years of study with the result that graduates in normal numbers are coming from this university this September, having completed 16 terms. No other wartime changes have taken place in curriculum, except that tropical medicine, hitherto optional, has been made compulsory. At St. Andrews a full teaching was instituted this summer for senior students with a view to expediting the date of the final examination from June of year to March.

Concentration of Teaching

For the fifth year some of the London schools remain part dispersed, but such dispersion as continues is due much to the emergency as to the fact that the new arrangements have been found, on the whole, more advantageous from teaching point of view. But there is a tendency to return to London. The departments of anatomy and physiology at the London Hospital, which had been temporarily transferred to Cambridge, have come back. Charing Cross students except for the first six months of the clinical period, they reside at Ashridge Hospital, now pursue the whole of their studies in London. The pre-clinical departments of the London School of Medicine for Women, after three years' exile at Exeter, are returning to London for this next session. The whole of University College Hospital Medical School has returned to its old premises in London, where the teaching clinical training are carried on much as before the war.

On the other hand, the pre-clinical school at Guy's is remaining at Tunbridge Wells, the clinical work being carried out at Guy's itself and at the sector hospitals in Kent. Thomas's still has its pre-medical and pre-clinical schools at Godalming, but the governing body of the school is making all provisional arrangements for the return of these departments to London by October, 1944. Incidentally its department of chemistry has become the department of biochemistry, the teaching of all the introductory subjects is being closely correlated with clinical teaching, so that the pre-medical and pre-clinical work is no longer a preliminary "nuisance" to fade into the limbo of things to be forgotten after the first and Second M.B. The early and late clinical periods are taken in London, where St. Thomas's has 170 beds, with patient and casualty departments on practically a permanent basis, and the periods of in-patient medical clerking, surgery, and midwifery are spent at the new hospital which has been opened at Hydestile close to the school premises at Godalming. St. George's undertakes all the clinical work except midwifery, at its old home at Hyde Park Corner it has a branch at Wimbledon with some 120 beds, and teaching facilities in specialized aspects of medicine and surgery are available. The clinical students of the London School of Medicine for Women continue to work at the Royal Free and at a number of hospitals in the sector in Hertfordshire. Incidentally, many more women seem to be taking to medicine. The West London Hospital Medical School now admits

omen students annually. The new quota at Oxford is seven omen students per annum—though this figure may be slightly increased for the year 1943-4—as against 64 men. A real difficulty which women students are up against concerns the London polytechnics, which train students up to their First M.B., but the students have to go elsewhere for their subsequent training. A number of women students, having passed their First M.B. at a polytechnic, find difficulty in securing places at Second M.B. schools. Numbers have been quoted—but are admittedly incomplete—which suggest that about half the women fail to get in anywhere.

The Importance of Paediatrics

The new importance of paediatrics is reflected in the arrangements at many schools. Manchester is considerably extending its instruction in this subject, which is now given throughout the whole of the clinical period. Birmingham has introduced paediatrics as a separate subject in the final examination. At Sheffield arrangements have been made for students to be in residence at the Children's Hospital for at least three weeks during their children's diseases appointment, this in addition to the usual residence of one month during each of the final medical and final surgical appointments and of two months during the midwifery appointment.

The Edinburgh Medical School continues to make a feature of child life and health. During the last three years clinical teaching in infant health has been given in the maternity pavilion at the Royal Infirmary, using as clinical material the newborn babies and the babies attending the hospital infant clinic, and this course has now been extended by the Faculty of Medicine to 20 meetings given to all students in the final year. The full programme of teaching in child life and health will now consist of 20 systematic lectures, a clinical course of three months (50 meetings) in diseases of children, given at the Royal Hospital for Sick Children, and the new clinical course in infant health (20 meetings) at the Royal Infirmary. The Faculty has also recommended that the subject be given a separate place in the final examination. These new arrangements give effect to the recommendation of the General Medical Council that in the final examination there should be a test of the candidate's knowledge of infant hygiene and of diseases in children.

Other Innovations

A feature of many of the reports from the schools is the new solicitude for student health. Thus, at Charing Cross a scheme already in existence for safeguarding students' health has been enlarged, and it is hoped by a reciprocal arrangement with the Royal Dental Hospital to make a further extension which will cover dental as well as medical examination and treatment. In this connexion some remarkable developments at Birmingham should be noted. The University of Birmingham recently made physical education compulsory for all students in their first year. This not only has familiarized the men themselves with regular and organized physical education but has provided the university with a means of giving the preliminary training which is essential if a reasonable proportion of the undergraduates are to pass the physical military efficiency tests for the Senior Training Corps. Medical examination is a prerequisite to the introduction of the tests, and for this purpose a university medical officer has been appointed, an appointment unique in British university experience. His chief care will be the routine examination of the men students, but he is to be concerned also with research into health standards at the university and with inspection of the physical education programme from the health point of view. A change which has affected medical students only is the university requirement, following an intimation from the War Office emphasizing the necessity for basic military training for candidates for commissioned rank in the R.A.M.C., that every medical student shall undergo two years' medical military training. Fifth- and sixth-year students will still normally be exempt, but courses of lectures are arranged for the men of the present senior years who under previous rules have escaped service in the Senior Training Corps.

Several of the schools report a considerable increase in the number of applicants for admission—Leeds and Cardiff in particular, the latter stating that the number is far greater

than the school can receive, and that the selection is in the hands of a special committee consisting of academic representatives from all the constituent organizations of the university. The unusual numbers, however, are a minor difficulty compared with other wartime urgencies and changes, and the schools are to be congratulated on the way in which they have dealt with the situation, meeting the national requirements without any real betrayal of educational ideals.

Postgraduate Facilities

The British Postgraduate Medical School at Hammersmith Hospital is carrying on its work as usual. All departments are active, but some modifications have to be made owing to reduced staff. Postgraduate students are accepted in the departments of medicine, surgery, obstetrics and gynaecology, pathology, and radiology. Intensive war courses are held every week, each lasting five days, and are attended by a large number of officers of the British and Allied Services. The School is also prepared, as a temporary measure, to accept undergraduate students who desire to fulfil the university requirements in obstetrics and gynaecology, hospital practice, and pathology. No undergraduate student is admitted direct; he is admitted only at the request of the dean of his school, and because of wartime difficulties arising therein. A considerable amount of research work is in progress at Hammersmith on shock problems, on hepatitis and jaundice, on silicosis, and on questions arising in connexion with haemoglobin estimation. The Medical Research Council Radium Beam Research Unit has been transferred to Hammersmith and the deep-therapy department of the hospital has been considerably enlarged. Students are accepted for the Part II requirements of the Diploma in Medical Radiology. The number of patients and the work of the hospital itself are probably greater than in pre-war days, more especially in the out-patient departments, which have expanded very rapidly.

MEDICAL STUDENTS ORGANIZE

FIRST YEAR'S WORK OF THE B.M.S.A.

The appearance above the horizon, a little more than a year ago, of the British Medical Students Association was an event of some importance to the future organization of medicine. Students of the universities have expressed their views through the National Union of Students, of which the medical schools have been active constituents. But the special problems around and ahead of the medical student seemed to call for a separate organization, and this was set up in a spirit of the utmost friendliness with the National Union, with which the B.M.S.A. remains in the closest and, to the new body, most helpful relations.

The circumstances which precipitated the formation of the new Association was an endeavour on the part of some London medical students, at University College Hospital, to formulate a memorandum on medical education with a view to its presentation to the Goodenough Committee. They began to feel themselves at a loss because at no point could they speak representatively and say that medical students held this opinion or that.

At the inaugural meeting in the summer of 1942 as many as 17 schools were represented by delegates, and the organization has since grown until now all the medical schools (except three in London) are constituent members. Nominally, therefore, it can be said to represent 90% of the medical student population in England and Wales, Scotland, and Northern Ireland—altogether 8,250 members. But this, of course, is far too flattering a picture, for among students as among their seniors there are large numbers who take their own individualistic line or are indifferent or hostile to collective counsel and action. The active spirits in the B.M.S.A. are not, in the main, the final-year men, who, quite understandably, are already beginning to detach themselves from student life, but are the students in the earlier clinical years. They include a larger number of women students than would be expected from the total proportion of women to men in the schools, and two students from the London School of Medicine for Women are members of the small executive committee. An obvious

disadvantage is that, apart from London, with its thirteen medical schools in close juxtaposition, and Glasgow, medical students are in small widely separated communities. At present the Paper Control prevents the establishment of a regular bulletin, and for Association news the good will of editors of school gazettes has to be solicited. The British Medical Association has acted as a kindly sponsor, assisting financially and as host.

Students in Conference

The inaugural meeting was followed by a congress last December, attended by 500 medical students, when the Minister of Health, Lord Moran, P.R.C.P., and Prof. J. A. Ryle (who is the honorary president) came to bless the undertaking. A visitor to that congress and to the first annual general meeting, which was held in July of this year, would have revised any former notion he might have held about medical students as irresponsible and rather "hard-boiled" persons. The students who took part showed themselves to be not only highly intelligent, which was only to be expected, but familiar with the implications of present-day movements in medicine and able to express their point of view well and succinctly. Incidentally the quality of the speaking and the capacity of the chairmanship set a good example to older assemblies. But it was the modesty of the students that made the chief impression. They made no claim to know better than, or as well as, their elders. They might well have asserted that as they were more affected than all but the newest qualified men by the shape of things to come they had a right to discuss these matters, but they preferred to regard it as a duty rather than as a right, recognizing that there are no rights where there are no responsibilities. On the other hand, having as yet no responsibilities, they felt that they could at least discuss the matters without the prejudice which arises as the result of experience. As one of them said, "We are still young enough and daft enough to work for a future that will be better than the present."

It must not be thought that the Association is a political body, at all events in the narrow sense of that word. As its president, Mr. David Pyke of University College Hospital Medical School, put it, it is faced with long-term and short-term issues. The long-term issues, like the Beveridge plan and certain aspects of student health, have inevitably a political tinge. But the B.M.S.A. also stands for immediate things over which there can be no controversy: objects designed to improve the efficiency and ameliorate the lot of students, suggestions for new instruction—the recent annual meeting passed a resolution asking for the inclusion in the medical curriculum of a compulsory course in normal psychology—and the encouragement of staff-student committees such as have already been set up at Leeds and other schools.

One enterprise upon which those concerned are to be congratulated is the arrangement of a series of lectures on war surgery, which are being given weekly this late summer in London by leading surgeons of Great Britain and friendly nations. The question of coeducation excites some controversy, though it is limited practically to London; but on another matter affecting their women colleagues the Association is asking what action it can—namely, the inability of many women who have taken their First M.B. at a polytechnic to obtain a place in a medical school for their Second M.B.

Student Health

Certain aspects of student health (concerning all students, not medical ones only) belong also to the short-term range of activity. These include propaganda directed towards making the general student body "health-conscious"; the extension of National Health Insurance to students (students are at present uninsured persons, and being members of a non-earning community they sometimes have difficulty in affording medical fees, though for medical students medical attention is usually freely available); the application to students of the mass miniature radiography scheme; and an immediate review and improvement where necessary of social conditions—including canteens, students' lodgings, and so on—within the universities by the students' organization in conjunction with the authorities. Other suggestions like the appointment by every university of a medical officer of health—following the recent example of Birmingham—come later.

The two outstanding achievements of the first year of new association were the memorandum on medical education and its own "Beveridge report." The memorandum was summarized in our *Supplement* of Jan. 9, 1943. It was presented later to the Goodenough Committee, which had a three-hour interview with the students' representatives, who explained the proposals. The committee was interested to find the student in favour of compulsory house appointments after qualification, provided adequate payment was made by the hospital. Other points stressed included the greater use of bed-municipal hospitals for teaching purposes and the advancement of student residences, not in the final but in the earlier years.

Discussions on the Beveridge plan have taken place in nearly all the schools, and the subcommittee has collated the opinions. The students have not restricted themselves to the consideration of Assumption B, but have had the whole report under review bearing in mind the increasing emphasis on preventive medicine and positive health. All the schools gave support to the plan as a whole and to the conception of the national minimum. But on the question of the comprehensive medical service there was a wide and healthy disagreement. A lively discussion at the recent annual meeting was crystallized into a long rather colourless resolution, but the lack of colour in the resolution was due to an attempt to assimilate the many contrasting hues. They agreed that a comprehensive medical service would be more effective only in conjunction with the Beveridge report as a whole, but that there was no need to await such completion, and that the comprehensive service would be of the greatest possible value to the community giving real financial security to the doctor and ensuring maximum democracy in the profession. Such a service would need to be under the control of the Minister of Health, a central council consisting mainly of professional workers. The students favoured health centres, and on the subject of payment the majority opinion appeared to be in favour of a combination of fixed salary and capitation fee with an upper limit to the number of patients under any one doctor.

Vaguely worded, of course, but the important thing is that these questions should be under continuing discussion. At the moment the fact of discussion which is important, and not, for the moment, the conclusions.

Correspondence

X Rays and the Colon

SIR,—I refrained from replying to Dr. E. Millington's letter (July 24, p. 117) as I did not think that many would interpret your short report of my address on functional disorders of the colon at the Proctological Section by thinning me guilty of stating that the radiological examination of the colon was of no value. But as Dr. Norman P. Hendle (Aug. 21, p. 247) has now made the same mistake I perhaps be forgiven for pointing out that I am hardly likely to hold such an opinion in view of the fact that I wrote my earliest paper on the x-ray diagnosis of a functional disorder of the colon in 1906, that I was the first in this country to describe the use of an opaque enema in 1909, and that the table still used as the standard for the normal rate of passage through the alimentary canal is founded on the observation of a group of Guy's students working with me in 1906.

It is none the less true that in the last six weeks I have seen two cases of carcinoma of the stomach clearly indicated by beautiful radiographs but missed by the radiologist who took them, one as long ago as last March, when the patient, a practitioner, was persuaded against his better judgment to accept his clinical diagnosis of malignant disease by the negative x-ray report. I have also seen a case of carcinoma of the plicocolon clearly visible but wrongly interpreted, and another in which pain in the right iliac fossa was ascribed to diverticulitis of the iliac colon when an obvious filling defect was present in the caecum. These diagnoses were made by four different radiologists, all of whom were on the staffs of large hospitals.

During the same period I have seen radiological reports ascribing symptoms to dropped stomach, dropped colon, c

pockets," cup-and-spill stomach, duodenal diverticula, and ucos colitis. Such diagnoses do great harm by helping to convert a patient with a mild functional disorder, who could be cured by the simplest psychotherapy, into a confirmed psychochondriac, nursing his mysterious but mythical malady, though, fortunately, surgeons are less easily persuaded nowadays than formerly to raise a "dropped" viscus, fix a movable one, and unfix a fixed one.

X-ray diagnosis will never be satisfactory until the clinical and pathological training of the radiologist is improved by insisting that no diploma should be awarded to a man who is not personally studied the anatomy and physiology of the normal subject, as I had the good fortune to do whilst demonstrator of physiology at Guy's in 1906-7 and that great pioneer of radiology Dr. A. E. Barclay did during the same period, and who has not held the appointment of house-physician in general hospital for six months.—I am, etc.,

Oxford

ARTHUR HURST.

Conditions for Good Work

SIR.—Dr. C. C. Cobb (July 24, p. 121) agrees that our great lack in general practice is "conditions that make good work possible," but emphasizes that money is one of the means to our end—a first-class medical service for all. I acknowledge his comment gratefully. Certainly the Ministry of Health will not expect first-class service for a third-class fare! Our main contention is that calm, thoughtful, and considerate handling of the sufferer demands time; and when the services of a highly trained professional man are concerned "time is money." Owing to the present meagre pay in vogue the panel doctor is often conscious of an unseemly rush in his interviews.

There has been ample airing of views on medical needs, and definite proposals from the profession are now due on reorganization of the bulkiest item—general practice. Does not private practice provide us with the working model of the first-class service ordained by Parliament? Of course, it needs adjustments with the growth of medical science and varying needs of the community, but, *in the main*, it has well stood the test of time and proves satisfactory to both doctor and patient. Unfortunately, the ideal of payment for service cannot be incorporated in the new national service as the masses could not afford it, so the capitation basis with Government assistance is necessary.

The average rate of pay per patient in private corresponds to about treble that of the National Health Insurance, and so the doctor gives the time and decorum required for a satisfactory interview. Nothing less can give the patients their due, and to get this the new national service must reduce the ration of patients accordingly and raise the capitation fee proportionately in order to maintain the doctor's income. The yearly remuneration per doctor may be little affected, but double the present total of doctors would be used and hence a doubled total expenditure by the Government will be necessary. Until this reform comes, the mere extension of the existing National Health Insurance standard of service, coupled with hospital services, to all below incomes of £420 does not satisfy the Beveridge plan, which stands for first-class service. In the remote rural districts the doctor is at a great disadvantage owing to professional isolation. All the more necessary is a man of ability above the average, and to attract him added remuneration is the just reward of the sacrifice involved.

The Government slogan repays reflection. "A first-class medical service for all unaffected by economic status" heralds the dawn of a new era in which our services will be regulated by the patient's pathology instead of his purse. This will satisfy one of the longings of the ardent spirits of medicine, many of whom are at present away with the Forces. After all, viewed down the microscope, cancer appears the same whether derived from one station of society or another. The pain from acute retention of urine is much the same in a peer or a porter. Again, granted decent remuneration, there will be time for the family doctor to pursue pathology to the end, whether it be at home, in the hospital, or the post-mortem room. By collaborative visits to hospitals, as at present in private cases at the nursing homes, there is ensured vital continuity of care for the patient and for study of the case. Such official association with hospital life guards against professional sequestration, of which the doctor so often complains at present, and keeps his knowledge up to date naturally, which is vastly superior to occasional artificial feeding by refresher courses. The latter may be inevitable for the rural practitioner.

The Government calls for a first-class tune and will pay the piper accordingly.—I am, etc.,

A. WILFRID ADAMS.

Service Doctors and State Medicine

SIR.—On several occasions recently supporters of a State Medical Service have told me that serving M.O.s as a body are whole-heartedly in favour of a State service. As I was in the R.A.M.C. myself at the beginning of the war and met many other M.O.s with whom I exchanged views, I thought this very doubtful.

I have lately received a series of letters from abroad, among them some from a friend of mine—Lieut.-Col. A. B., R.A.M.C. He tells me that after nearly four years' experience of a State service he and his officers are so tired of it and dissatisfied with it that they hope and pray the B.M.A. will oppose the establishment of a whole-time State Medical Service in England tooth and nail. He further voices a very common grouse of Service M.O.s, particularly of senior officers who are increasingly concerned with administration, when he says: "During nearly four years of war I have done perhaps two months of real medicine, and I feel that I am beginning to forget what I once knew. What is to become of us—and our patients—when this is all over?" What indeed? I would like to suggest that the B.M.A. should press, with all the strength of which it is capable, for the establishment of a three-months refresher course, on full pay and allowances, for any Service M.O. who wishes to take advantage of such a facility when hostilities are over.

In his latest letter Col. A. B. says that he and his officers have discussed again Assumption B of the Beveridge report, and all, without exception, are utterly opposed to its implementation unless all the other sections of the report are also implemented. They further wonder how "positive health" can be achieved by a full-time State Medical Service unless housing, nutrition, and education are first dealt with and placed beyond reproach. One of his officers declared that if a State service were established in England he would prefer to stay in India and bring his wife and children out to join him. The youngest of his officers, who joined the R.A.M.C. directly from hospital, was perhaps more opposed to State service, with its strangling red tape, than any of them, and reported that on board ship on the way to India his medical draft held a meeting to discuss the threatened changes in practice, and on a free vote unanimously passed a resolution rejecting the idea of a full-time State Medical Service.

Col. A. B. ends by saying that in his experience serving doctors feel that no such fundamental change in methods of practice should even be discussed until they have returned home, and they completely fail to see why there should be this sudden urgency about the matter.

This is also the general sense of my correspondence with other doctors in the Forces, and I feel that I am not far wrong in stating that there is as large a percentage of them opposed to State Medical Service as there is among those of us in civilian practice, and that means a definite majority in favour of the retention of professional freedom.—I am, etc.,

VICTOR RUSSELL.

The Future Health Services

SIR.—It is rather confusing to find some of your correspondents still decrying the Beveridge report, which is more or less common ground, without suggesting convincing alternatives to "State" service. What has become of the scheme which last September the Representatives thought to have well and truly launched for suitable working out by the Planning Commission? If it has been stillborn, the term is not "evolution" but "decay." For the B.M.A. to finish up, as seems possible, with simple extension of N.H.I., and no more, would be, I submit with all respect, a poor result for everyone.—I am, etc.,

Atherton.

A. PATTON.

Public Opinion on Health Services

SIR.—Your correspondent Dr. W. N. Leak (Aug. 21, p. 243) expresses his disagreement with my letter of Aug. 7 in a manner that amply justifies your having printed it. He says: "The doctor's duty is to speak and act as he thinks right without fear or favour." Of course it is desirable "to ensure that his opinion should be free from outside pressure." Surely

we all agree most heartily so far as these remarks apply to our professional relationships with patients; although, personally, I fail to see how this ideal can be achieved in any system where the doctor's remuneration is directly proportional to the extent to which he pleases each individual patient. Far too often the doctor is pressed to bow to what in relation to his professional opinion might legitimately be termed "ill-instructed popular clamour." But that is not a legitimate description of public opinion in relation to the Beveridge report. Moreover, in that connexion the doctor is not in "his privileged position," being at most no more than an experienced adviser, while as an interested party he is certainly not in a favourable position to sneer at public opinion in the contemptuous manner adopted by Dr. Leak.

We may be entitled to hold our own opinions about democratic government, but no one can positively refuse to recognize its reality or any of the other fundamental facts of the situation. May I, therefore, be permitted to repeat that it is the people's representatives in the House of Commons and not members of the medical profession who are 'shortly going to recommend and carry out reforms. Also they are doing this in response to what Dr. Leak calls "ill-instructed popular clamour" and not in order to quell any spontaneous revolt of the medical or even insurance circles against their present lot. How can any arguments be expected to hold water where the actual facts of a situation are being dismissed as "pseudo-realistic"?—I am, etc.,

Eye, Suffolk.

J. SHACKLETON BAILEY.

Diabetic Retinitis

SIR.—Mr. J. H. Doggart asks (Aug. 14, p. 212) if any of your other readers have had the happy experience of Dr. George Graham (July 24, p. 115), who has seen *retinitis* improve under diabetic control, whereas Mr. Doggart has seen no improvement in *vision* from good treatment. Our experience supports both their views, because they are probably referring to different phases of the same disease. By the time a case reaches an ophthalmologist for *defective vision* the disease is already well advanced, and usually shows extensive exudates which can rarely be affected or removed by treatment. But physicians who examine their diabetics' eyes carefully as a routine see much earlier stages of retinitis, as haemorrhages and small exudates may be seen for 5 years or longer without appreciably affecting the vision. The earliest stages of small haemorrhages, in very numerous ones, may completely disappear under vigorous treatment with insulin—whether they may disappear without treatment we do not know.

We have not worked out any accurate figures in our patients, but of some 1,500 cases with diabetic retinal lesions some 50 have lost all haemorrhages or show an occasional small one from year to year with unaffected vision. The vast majority, many with large exudates when first diagnosed, become slowly but progressively worse, total blindness being, however, rare; but an unfortunate small minority, often fairly young and well controlled, mysteriously develop retinitis proliferans with rapid loss of vision. It is significant, we think, that the comparatively few adolescents we have seen with retinitis have been most wildly uncontrolled cases, the retinal lesions having usually developed during their worst phase and been checked by better control of their diabetes. We think, therefore, at present that careful diabetic treatment is most important, may even remove the condition, but more often checks its progress.—We are, etc.,

WILFRID OAKLEY.

Anaesthesia for Laryngofissure

SIR.—In view of the recent correspondence on anaesthesia in laryngofissure I think it worth recording my experience in one case quite recently.

The patient was a man aged 68 years with a small localized squamous-celled carcinoma on the right vocal cord. Laryngofissure was decided upon and I was asked to give the anaesthetic. The following is the procedure I worked out and adopted. For pre-medication the patient was given 1/100 gr. atropine one hour before operation, together with pot. brom. 40 gr. orally. In the theatre the patient was made to gargle with 5 c.cm. 2% anethaine solution (Glaxo), which was subsequently swallowed. Three c.cm. of 2%

anethaine was then injected intratracheally through the cricothyroid membrane, and two more injections were then made into the region of the superior laryngeal nerve; these extended from the cricothyroid membrane upwards and laterally for about 3 in., and were made up of about 5 c.cm. of 1% novocain and adrenaline (strength: adrenaline mv and 1% novocain 1 oz.). I stress the fact that adrenaline was used and will refer to this later.

Anaesthesia was then induced with 1/2 g. intravenous sodium pentothal, which I then followed by introducing a No. 5 Magill's rubber endotracheal tube through the nose, passing it into the trachea with a Magill's direct-vision laryngoscope. Inhalation anaesthesia was then continued using gas, oxygen, and trilene as anaesthetic agents.

The operation then commenced and throughout I experienced no trouble whatsoever. Tracheotomy was not performed, as, in the opinion of the surgeon, it is an undesirable measure if it can be avoided from the point of view of subsequent sepsis and distress to the patient. The thyroid cartilage was split and the trachea packed off round the endotracheal tube with gauze. During the whole of these proceedings no spasm occurred, and after the operation there was a minimum of bleeding. The wound was closed without drainage. The patient was conscious on the table within a few minutes of stopping the anaesthetic; the tube was removed and an airway inserted. On returning to bed the patient was immediately put in a sitting posture, showing no ill effects. There was no vomiting and he has made remarkable progress.

I stressed the use of adrenaline as it may be used in the presence of trilene, unlike chloroform; also another important fact is that diathermy may be used with safety in the presence of trilene as an anaesthetic agent.

In my opinion the above method seemed eminently satisfactory both from my point of view and also from the point of view of the surgeon. I would like to express my thanks to Mr. W. H. B. Magauran, who performed the operation, for allowing me to record this case.—I am, etc.,

Cheam, Surrey.

A. M. B. TOMPKIN.

Artificial Insemination

SIR.—The interest of medical men and women cannot fail to have been stirred by the recent discussion in the House of Lords on the problem of breeding by artificial methods, particularly as applied to human beings. As a worker in this specific branch of sterility and infertility I beg a small space in your paper in order to place a few thoughts on this extremely important and far-reaching subject before some of my fellows.

First we must note that, whatever knowledge the various speakers may or may not have had, on this occasion not one had thought of, or even heard of, any serious argument in favour of artificial insemination. Such a one-sided discussion savours if not of ignorance at least of prejudice. The medical profession must be armed and on guard against any premature attempts by the lay public to interfere with methods of treatment which are in their infancy and might if unreasonably suppressed postpone the alleviation and happiness of many thousands of individuals, and even in this case have ultimate serious effects upon the nation as a whole.

The facts I offer are these. First, actual individual sterility and subfecundity, both male and female, are on the increase. The urgency of the problem of combating the falling birth rate should always be present in our thoughts when weighing this question from any angle. Secondly, in this country the vast proportion of inseminations are carried out upon the wife with the semen of her own husband. The rare cases where a semen donor is used are those in which the sterility of her husband is absolute and incurable, free consent of both husband and wife being given. Thirdly, the method, especially in the non-donated cases, is not so artificial as the ignorant suppose. The female function must be normal to achieve success, and wherever possible the method of choice used by my colleagues and myself is that of insemination of the cervix from the vaginal pool following normal intercourse.

The Bishop of Chichester is reported to have said that the relationship in regard to the home and family between the sterile husband and the wife inseminated with donated semen would be extremely anxious and extremely unhappy. Why? Does the good and affectionate husband with a happy home to offer to a child wish to bring into such a home the shadow of his deliberate and intentional frustration of his wife's best and most powerful instinct? It is useless to answer this question by suggesting that adoption meets her case. No woman who has chosen to bear her own child would exchange this greater joy for anything less. The greatest psychological obstacle that the married couple has to surmount in such cases is the knowledge backed by medical evidence of the husband's sterility. If their mutual respect and regard can surmount this, is there any-

ing more likely to cement their relationship than the mutual responsibility for the wife's child granted her by her husband's generosity?

For centuries woman has borne the blame and burden of the barren marriage, and surely it is time man accepted his part of the responsibility. Only by suppressing the true facts behind a barren marriage can one avoid the inevitable desire of the wife to seek a way out of an intolerable situation. If we deny her a good one she is often tempted to a bad one.

I am not really writing purely in defence of what I have just described as "a good way out," but I earnestly desire that the medical profession will weigh all evidence—medical, social, and ethical—and decide the question for themselves, resisting at the meanwhile all efforts, threats, persuasions, propaganda, and the like calculated to frighten or cajole them into a premature retreat.—I am, etc.,

London, W.1.

MARY BARTON.

Artificial Vitreous Body

SIR.—Recently I was asked to see a patient, a dockyard worker, with a discharging eye socket. On examination I found the conjunctiva was deeply pigmented and there were black bands visible through gaps in the conjunctiva, which at first I took to be fossilized stitches. Then it occurred to me that it might be a silver-wire artificial vitreous body. X-ray examination confirmed this. With great difficulty I removed the wire cage. The interest is historical. Personally I have never seen one of these objects before. In this case the cage was inserted by Dr. Rolston at the Royal Albert Hospital, Devonport, on May 6, 1908, following enucleation for a perforating injury of the eye. The instrument—Landmann's artificial vitreous body—is illustrated in the 1930 instrument catalogue of Messrs. Allen and Hanburys, No. 6283.

In this connexion Mr. C. B. F. Tivy of Plymouth gave me a very interesting note. He was asked to see a patient in consultation some years ago. The conjunctiva lining the empty socket was stained a deep black from argyrosis and the patient was complaining of failing vision in the remaining eye. Mr. Tivy came to the conclusion that the failing vision was due to toxic amblyopia following absorption of silver. The silver cage was removed from the socket and the vision in the remaining eye then returned to normal within a short while.—I am, etc.,

Gloucester.

J. D. J. FREEMAN.

Skin Sensitivity to Sulphonamides

SIR.—I read with interest the medical memorandum (April 3, p. 414) on the subject of dermatitis following local sulphanilamide therapy. I have had experience of two cases of quite severe dermatitis following local and oral administration of sulphanilamide. In both the reaction followed within 48 hours of changing from local to oral administration of the drug. The notes below may be of interest to some of your readers.

Case 1.—The patient had been under treatment for some 10 days with ung. sulphanilamide for facial impetigo with little or no improvement in the condition. Having obtained good results previously with oral treatment I decided to stop the local application and give the drug by mouth. The following morning the patient reported with a very severe skin reaction. The eruption was like a mixed morbilliform and scarlatiniform rash covering the whole body surface, but most marked on the face, neck, upper portion of the back, the extensor surfaces of the legs and forearms, and the palms and soles. There was a considerable amount of irritation associated with the rash, but no general systemic reaction. The sulphanilamide was stopped and calamine lotion applied. The rash disappeared in 3 to 4 days, and after about 10 days the skin of the palms and soles peeled off completely.

Case 2.—The patient was under treatment for facial impetigo with a local application of 10% ung. sulphanilamide, and after 12 days' treatment without improvement I decided to adopt the oral route. A total of 8 g. was given in 48 hours, and before the end of the second day an irritating erythematous rash had appeared, in this case confined mainly to the back of the neck and the extensor surfaces of the forearms. In this instance, however, papulae developed in addition to the rash, and these subsequently became pustular; 5 to 6 days later bullae appeared on the right index finger and left thumb on the extensor surfaces. The sulphanilamide, of course, had been stopped when the skin reaction

occurred, and treatment with saline and calamine lotion eventually cleared the condition up. Again the skin on the palms peeled off.

Both these patients had fair hair and a fair complexion and therefore, probably, a rather sensitive skin. The first case was severe in the extent of the eruption; the second, although less extensive, was more severe locally. I wonder if any of your readers have had similar experiences of dermatitis following a change from local to oral administration of sulphanilamide.—I am, etc.,

L. G. TULLOCH.
Flight Lieut.

M.E.F.

SIR.—Fowlkes, Pepple, and Vaughan (*South. med. J.*, 1942, 5, No. 11, 1015), describing a case of fixed erythematous eruption following the administration of sulphanilamide, state that only two other cases have been noted. Hence the following personal experience is worth recording.

I used sulphanilamide and sulphapyridine before either were generally marketed, and administered normal doses to myself at various times for "sore throat." On taking some sulphapyridine in the autumn of 1941 (a lapse of about 9 months since the previous dose) a curious skin eruption was noticed. This occurred in four separate and distant places on the body. The areas concerned were each approximately 3/4 in. by 3/4 in. in extent and raised about 3/8 in., red and intensely irritating. The drug was stopped, and in about 5 days the areas had subsided, leaving a brownish discoloration of the skin which eventually took over 12 months entirely to disappear. An identical result was obtained when a repeat of the treatment was attempted some weeks later.

As a matter of interest trials were made during the following six months both with very small desensitizing doses of the drugs and with alternative makes and types such as streptocid, protosil, and sulphapyridine. Nothing made any difference. One-sixth of a tablet of protosil caused the eruption. Injections of adrenaline up to heroic doses had no apparent effect on the areas, which were exactly the same in each case, as were the symptoms.

The cause of this phenomenon remains unexplained, though it is possible that treatment for tetanus with large quantities of serum (which, among other things, caused acute oedema of the glottis) 20 years before may have some connexion. Fortunately my infrequent sore throats are even more rapidly, if more prosaically, cured by sodium salicylate.—I am, etc.,

London, W.1.

NEVIL LEXTON.

Early Recognition of Cancer

SIR.—The new Cancer Act will mean a great step forward in the treatment of cancer. But is there not something we can do towards earlier recognition of the most sinister and probably the most important of all diseases by education of the public? Adequate periodic medical examination, now happily receiving attention, would do much, but there is something simpler that can be done here and now—or at least as soon as war ceases. Is it not time that there existed an authoritative popular booklet on the earliest recognizable symptoms of cancer in various organs—"put across" to the public by expert propaganda of the right type? If we can spend millions on elaborate treatment of established cancer would it not be a sound investment to spend a few thousands on catching it in the early curable stage? Curable cancers, speaking generally, are those in accessible organs—skin, genitalia, breast, uterus, mouth. They can and should be caught young; and the public can and should be systematically taught to be on the look-out for them. If treated in time they yield most satisfying 5-year-cure figures of the order of 75 to 95%.

I know it will be objected that an educational campaign might cause cancer neurosis. I believe this argument to be at best irrelevant and at worst positively dangerous. I think it was Ewing who said that cancer-consciousness ought to be part of civilized living, and that any such neurosis would apply only to those already neurotically disposed. Why should we sacrifice the greater good to the lesser?

An educational campaign would reach first the more intelligent classes of the population, but the gradual improvement in the general educational level that we are entitled to expect would make the campaign yield ever-increasing rich dividends.

I think, therefore, that the time is over-ripe for taking this elementary but fundamental step, and that such bodies as the Ministry of Health and the British Empire Cancer Campaign should give it their urgent attention.—I am, etc.,

JOSEPH WALTER.

Assistant Medical Director, Sheffield Radium Centre.

Specific Gravity of Cerebrospinal Fluid

SIR,—Mr. Etherington-Wilson (Aug. 7, p. 165) has reminded us that the cerebrospinal fluid when examined at body heat has a lower specific gravity than at room temperature. Accurate determination of this is of little interest except to those who use spinal anaesthesia. To those who use light nupercaine (1:1,500) for this purpose the knowledge is of some importance, for the specific gravity of the two fluids is close. It is obviously important to know whether the fluid which is injected into the spinal canal is lighter or heavier than the fluid into which it is injected. Mr. Etherington-Wilson's results suggest that in the majority of patients the specific gravity of the cerebrospinal fluid lies between 1.0030 and 1.0035. The producers of nupercaine, however, state that the light solution has a specific gravity of 1.0036 at body temperature. This would make it hyperbaric for the majority of patients and hypobaric for only a minority. It would be even more hyperbaric if used at room temperature instead of at body heat as is sometimes done. As this result is not borne out in practice it would seem that one of these figures is incorrect.—I am, etc.,

Staines County Hospital.

J. K. HASLER.

Research in Senile Diseases

SIR,—I was very pleased to see the article by Dr. S. Cieman on the possibilities of research in senile diseases (Aug. 21, p. 239). We are, on the whole, very ignorant about the diseases of old age. Since the senile portion of the population is likely to increase rapidly during the next few decades this ignorance is a matter for anxiety. Some research has admittedly been carried out on the problems of cancer, of endocrine function and dysfunction, and of vitamin requirements, but the commoner senile disorders have been neglected. The most frequent cause of death in the aged is cardiovascular disease, which has been little investigated. The digestive disorders of the aged are yet only ill understood.

It is time for attention to be paid to these matters. Let us hope that the "Club for Research on Ageing," or some other body which can interest research workers and investigators, will find a way to open an assault on the problems of old age. There is material in plenty throughout the country; let us now pay attention to this matter.—I am, etc.,

Leighton Buzzard.

TREVOR H. HOWELL.

H 11 for Cancer

SIR,—I have read your correspondence in the *Journal* of July 31, p. 149, with some interest.

When I was surgical registrar and pathologist to the Hospital for Women, Soho Square, London, W.1, I tried Thompson's early extracts upon inoperable cases of carcinoma. All cases were under independent observation by other members of the medical staff of this hospital. I formed the conclusion that the extract was harmless and seemed to exercise some inhibitory action in certain cases. I still keep in touch with one instance of carcinoma of the vulva, alive and well after ten years, treated with these early extracts and now with the new H 11: I may add that x-ray treatment, radium, and surgery had failed in this case.

Since the outbreak of war I have been out of touch with Mr. Thompson and my research activities have had to be abandoned, but, in all fairness to Mr. Thompson, I think this letter should be published.—I am, etc.,

Anglesey.

JOHN H. HANNAN.

Medical Boarding for the Merchant Navy

SIR,—The letter of Dr. S. H. Waddy (Aug. 21, p. 248) calls attention to one aspect of a large problem. His experience seems to have been unfortunate and to have led him to the belief that more physical fitness and discipline are necessary if the status and morale of His Majesty's Merchant Navy

are to be more worthy of the name. In support of this surprising statement he cites cases of suspected malingering and the impertinence of a youth. In every flock there is a black sheep, and the Merchant Navy is a very large flock, but the tone of his letter suggests that the apparent blackness of some sheep may have been due to his wearing spectacles "smoked" by annoyance.

May one who for thirty years has enjoyed intimate contact with officers and men of the mercantile marine lodge an emphatic protest against this estimate of their discipline and morale? It is largely the sturdy independence of the sailor that has made his reputation, but this very quality makes him suspicious of any attempt at regimentation and control, whose advantages he cannot at once appreciate. Explanation and persuasion are essential preliminaries to his acceptance of any new scheme. However well meant and however useful such a scheme may prove to be he will be unwilling to co-operate if it seems to interfere with what he regards as his rights and privileges as an individual.

The idea of a "properly constituted medical board and a compulsory card" has much to recommend it to the non-sailor; to the sailor himself it may be unwelcome. Those of us (medical men and laymen alike) whose duty and privilege it is to care for the sailor have given very careful thought to the advantages of a regular Merchant Navy medical service charged with the care of the sailors' health in its broadest aspects, providing skilled medical and nursing attention ashore and afloat, adequate convalescence, and complete rehabilitation, for there is no "light duty" at sea. We are concerned, too, to ensure the early detection of disease or disabilities and the provision of protection against illness of all kinds.

Dr. Waddy's suggestions are, therefore, of peculiar interest and value at the present time, but it is of importance in carrying out the changes at which he hints that a policy of gradualness should be adopted. In view of the difficulties involved it would seem unwise to try to force reforms too zealously and rapidly upon a Service whose members are entitled to grant or to withhold their co-operation.—I am, etc.,

Dreadnought Hospital, S.E.10.

C. E. SUNDELL.

"Milk" and "Nurses"

SIR,—Government policy is arraigned by two of your correspondents in the *Journal* of Aug. 21 on quite different counts, but the combination is interesting and provokes thought.

Milk is still to be supplied to the public in a potentially poisonous condition, complains Dr. Watkins (p. 247), and will continue to carry disease to the children who matter so greatly to us all to-day.

Hospital beds, where the sick we go on producing must be cared for, are in ever greater demand, but here we are up against the other problem—insufficient nurses. In vigorous terms Dr. Mavor (p. 248) denounces the proposed remedies and urges young recruits to nursing to evolve others. Surely they will never find a better one than so many of their contemporaries have already adopted—namely, the stay-out strike. It is we, the public, who have failed and must face the consequences of our apathy. If we exploit the health and freshness of one section of our young in caring for another section, who fall sick because of our mishandling, do we deserve to emerge from the vicious circle we have created?—I am, etc.,

Moor Park, Northwood.

ESTHER CARLING.

Hospitals and medical schools in the United States are organizing affiliated hospital units for civil defence, and already over 1,000 doctors and dentists have applied to be associated with them. The staff are commissioned in the "inactive" reserve of the U.S. Public Health Service (which is the responsible Government Department) with ranks equivalent to lieutenant-colonel, major, or captain in the Army, but they do not wear a uniform until called to active duty in an emergency (air raids, etc.), and serve only in their own or neighbouring States. When called for active service they receive the pay and allowances of the equivalent Army rank. The *Journal of the American Medical Association*, in a recent issue, assures doctors that they need have no fear that they will be involved in any other responsibilities to the Public Health Department if they undertake this emergency work. Their duties will be strictly "limited to those which they have agreed to assume as a result of enemy action."

Obituary

F. J. CLEMINSON, M.Ch., F.R.C.S.

we announce with regret that Mr. F. J. Cleminson, the distinguished oto-laryngologist, died from pneumonia on Aug. 21. He was consulting aural surgeon to the Middlesex Hospital, and honorary director of research at the Ferens Institute of Oto-laryngology, founded in 1927 by a benefaction of his uncle, the late Right Hon. T. R. Ferens of Hull, chairman of Reckitt and Sons, Ltd., who gave £20,000 to the Middlesex Hospital Medical School for that purpose.

Frederick John Cleminson was born in 1878, son of the Rev. J. R. Cleminson of Hull. From Kingswood School, Bath, he went to Gonville and Caius College, Cambridge, with a scholarship, and gained first-class honours in both parts of the Natural Sciences Tripos, taking his B.A. in 1901 and M.A. in 1904.

Between those years Cleminson was a successful teacher, living in Caius as Shuttleworth Student. After clinical study at University College Hospital he took the B.Ch. in 1909 and the M.Ch. in 1913, having held several house posts at U.C.H. and a clinical assistantship in the ear and throat department of the Hospital for Sick Children, Great Ormond Street.

During the last war he served with a temporary commission in the R.A.M.C. in France and Salonika. After his turn to civilian life it became clear that his gifts were to find full expression in the specialty to which he gave the rest of his career. In due course he was appointed aural surgeon to the Middlesex Hospital and the Evelina Hospital for Children, and surgeon to the Throat Hospital in Golden Square.

Although private work made heavy claims on his time and energy Cleminson's professional life was centred on the Middlesex Hospital, where his flair for teaching and scientific enquiry proved an inspiration to students and colleagues. The Ferens Institute gave him the means and opportunity for valuable research into the aetiology of diseases of the ear, nose, and throat. The prevention of deafness made a strong appeal to his practical mind, and his command of lucid English was well shown in the article on hearing aids contributed to this *Journal* in 1938 for the series on "Treatment in General Practice." A member of the B.M.A. since 1911 he took an active part in the work of the Hearing Aids Committee, which sat at headquarters from 1937 onwards. He had been secretary of the section of Otology at the Annual Meeting of the Association in 1922, and vice-president of the Section of Oto-rhino-laryngology in 1929; he was also a past-president of the Otological Section of the Royal Society of Medicine. Early in 1938 he found no strain of operating practice too much and devoted himself to academic study and research. The war cut down these activities through the enforced closure of the Ferens Institute, with which the name of F. J. Cleminson will always be associated as its moving spirit and first director of research.

We are indebted to a friend and colleague for the following tribute:

Although his health, originally undermined at Salonika, had been deteriorating for several years and he had for long been more and more restricting his activities, the death of "Clem" will bring sorrow to many, for among his numerous admirable qualities loyalty to his friends was not the least. Another was his genuine and deep affection for children, for whom he had real understanding, and although he work which he finally adopted was mainly surgical he would probably have been happier as a physician. At heart he was a physiologist, and he has been incorrectly described as a demonstrator of anatomy at Cambridge. He taught physiology there for several years before he qualified, so that he completed his hospital training after late. It was therefore not until the close of the war of 1914-18 that he had finally to settle upon some definite line, and he aural departments at U.C.H., under Herbert Tilley, and at Middlesex gave him his opportunity. It was, however, the physiology of the ear rather than its surgery which really interested him. Of aural neurology and everything connected with the problems of deafness he had a profound knowledge, though he did very little himself that was original. His great contribution was the foundation of the Ferens Institute, and he had the instinct of collecting the right men to work there. His administrative capacity, with the pathological, histological, and photographic technique of which Albert Gray was master, made a perfect combination, and enabled Gray to produce some of his finest work. Though both have gone,

the foundation was well laid and the work will surely continue with success in other hands.

For a few years Magnus and De Kleyn made Utrecht the Mecca of those interested in the physiology of the ear, and this soon attracted "Clem," who made many pilgrimages to Holland. De Kleyn, still at work in Amsterdam, remained always one of his closest friends, and with the late Prof. Benjamins and Gray they founded the Collegium, an international club which had its headquarters at Groningen. This institution, now rendered inanimate by war, was dear to "Clem," who was indeed filled with admiration for everything Dutch. Although he wrote very little and was too shy to speak in public, even at a professional meeting, if he could possibly avoid it, he yet managed to do a vast amount to promote the activity and advancement of his own branch and to alleviate the trials of the deaf. This brought him a wide and well-merited reputation. His gentle nature was lacking in the ruthless streak required of the successful surgeon, but he was much loved by his patients and still more by his friends. He knew everything about sailing, almost everything about motor-cars, a great deal about birds; he enjoyed a shoot, and dispensed an elegant hospitality in which the true kindness of his character showed itself. Had it not been for an excess of modesty he might have occupied an even higher professional position than he actually attained.

Universities and Colleges

UNIVERSITY OF LONDON

On the occasion of President Roosevelt's visit to Ottawa on Aug. 25 the Chancellor of the University of London, the Earl of Athlone, on behalf of the Senate, conferred on him the degree of Doctor of Laws *honoris causa*. An Oration was read by Dr. C. H. Best, F.R.S., professor of physiology at the University of Toronto.

UNIVERSITY OF BIRMINGHAM

A course of five lectures on "Heating, Lighting, and Ventilation" for industrial medical officers will be held at the Medical School, Hospitals Centre, Birmingham 15, from Sept. 20 to 24 inclusive; they will be given at 4 p.m. in the Physiology Lecture Theatre. On Sept. 20 and 21 Dr. T. Bedford will lecture on "Heating and Ventilation," and on Sept. 22 on "The Determination and Control of Atmospheric Pollution." On Sept. 23 Mr. H. C. Weston will lecture on "Sufficient Lighting—Illumination and Visual Capacity for Work," and on Sept. 24 on "Suitable Lighting—Environmental Brightness, Glare, Diffusion and Shadow, Colour." The fee for the course is £1 1s., which is payable in advance to the Secretary of the University, Edmund Street, Birmingham. Nurses engaged in industry are invited to join the course at a fee of 5s.

SOCIETY OF APOTHECARIES OF LONDON

At a meeting of the Court of Assistants held on Aug. 17 Sir Stanley Woodwork was elected Master for his third consecutive year of office, Dr. J. P. Hedley Senior Warden, and Dr. Hugh F. Powell Junior Warden.

The following candidates have satisfied the examiners in the subjects indicated:

PATHOLOGY, BACTERIOLOGY, AND FORENSIC MEDICINE.—D. A. Cox, C. M. F. Fiducia, I. D. Henderson, J. R. S. Jackson, M. W. Johnston, J. M. Macdonald, J. Middleton, J. C. F. Poole, A. M. Rajah, N. Sachse, J. R. S. Scarlett, J. C. Stevens, M. N. Tata, J. K. Wilson.

SURGERY.—D. A. Cox, B. A. Gould, R. K. Haslam, R. J. H. Hodges, R. J. C. Hutchinson, F. J. Martin, J. C. F. Poole, A. M. Rajah, N. Sachse, J. R. S. Scarlett, W. M. Thomas, J. K. Wilson.

MEDICINE.—M. A. Hamdy, J. M. Macdonald, J. C. F. Poole, C. D. Sanders, N. Sachse, J. H. S. Scarlett, R. N. Theakston, W. M. Thomas, J. K. Wilson.

MIDWIFERY.—S. R. Abrams, M. Benjamin, A. E. Bernstein, P. D. Bryant, K. R. J. Coates, D. I. T. Edwards, T. H. Eustace, C. C. Gould, E. D. C. Jones, R. A. Leeming, H. R. Mohammed, J. C. F. Poole, A. M. Rajah, N. Sachse, W. M. Thomas, J. K. Wilson, H. M. Wolf.

The Diploma of the Society was granted to J. D. Henderson, B. A. Gould, G. R. S. Jackson, J. M. Macdonald, J. C. F. Poole, A. M. Rajah, N. Sachse, C. D. Sanders, J. H. S. Scarlett, W. M. Thomas, and J. K. Wilson.

The Services

Surg. Cmdr. F. E. Stabler, R.N.V.R., has been awarded the R.N.V.R. Officer's Decoration.

CASUALTIES IN THE MEDICAL SERVICES

Presumed Killed in Action at Sea.—Major R. Clarke, R.A.M.C. *Prisoners of War.*—Lieut. S. Campbell, R.A.M.C., War Subs. Capt. M. C. Dickson, R.A.M.C., Temp. Major J. L. Gilloran, R.A.M.C., Fl. Lieut. A. N. H. Peach, R.A.F.V.R., Lieut. D. R. McPherson, R.A.M.C., War Subs. Capt. A. W. G. Sutherland, R.A.M.C.

Died.—Major H. N. Osborne, R.A.M.C., Capt. R. Wilson, R.A.M.C.

No. 32

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 14.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths from each infectious disease, are for: (a) The 126 great towns in England and Wales (London included), (b) London (administrative county), (c) The 13 principal towns in Eire, (d) The 13 principal towns in Eire, (e) The 13 principal towns in Eire.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week reviewed the notifications of measles fell by 427 and of acute pneumonia by 1 but the figures for whooping-cough and dysentery rose by 27 and 27 respectively.

The 38 more cases of scarlet fever were the result partly a small rise in London and the South-Eastern Counties .. notifications in the combined area) and partly of a rise of 31 in Lancashire. The only decrease of note was 70 fewer cases notified in Yorks West Riding. The downward trend of the past four weeks gave place to a general rise in the incidence of whooping-cough, especially in Lancashire and London, with 51 and 28 more cases respectively. There were only a few exceptions to the falling trend of measles—for example, 48 more cases in Essex. The biggest decreases were in Norfolk 74 and in London 38.

The principal of several outbreaks of dysentery during the week were in Kent, Malling R.D. 12; Essex, Dunmow R.D. 10; Nottinghamshire, Nottingham C.B. 8; Wiltshire, Westbury U.D. 8; Suffolk, Blyth R.D. 8; Caernarvonshire, Bangor M.B. 6 and Llyn R.D. 5. In London notifications went up from 13 to 20, and in Lancashire down from 18 to 9, and in Gloucestershire from 17 to 6.

In Scotland the only disease with a noteworthy change in incidence was scarlet fever, with 45 more cases, due to a general rise in the south-eastern area. The high level of dysentery was maintained, 100 cases (an increase of 5 over the previous week) being notified.

In Northern Ireland, according to the daily press, 13 cases of typhoid have been notified in Belfast. Cases have also been reported from other towns.

The Week Ending August 21

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,516, whooping-cough 2,015, diphtheria 527, measles 1,049, acute pneumonia 312, cerebrospinal fever 38, acute poliomyelitis 16, dysentery 198, paratyphoid 8, typhoid 13.

Medical News

A meeting of special interest to medical practitioners has been arranged by the Association for Scientific Photography and will be held in the clinical lecture theatre on the first floor of the Middlesex Hospital, W.1, at 2.30 p.m. on Saturday, Sept. 18. The subject of the meeting is "Clinical Photography." Short papers will be read by Mr. T. P. Kilner, F.R.C.S., Miss Hilda Marsden and Fl. L. H. Mandiwall, M.B., L.D.S. (chairman). The meeting will deal specifically with the clinical photography of patients. Surgical techniques, orthopaedics, pathology, etc., will be excluded. The Association for Scientific Photography invites all interested medical practitioners to attend the meeting and join in the discussion.

Dr. Donald Johnson, standing as a Liberal Independent, lost the Chippenham Parliamentary by-election by 195 votes. Mr. David Eccles, the successful candidate, standing as a Conservative and National Government supporter, is a son of Mr. W. McAdu Eccles, F.R.C.S., and son-in-law of Lord Dawson of Penn.

A specialized library has been established for the use of members of the Institute for the Scientific Treatment of Delinquency. A twenty-two-page index of authors has just been issued, and a subject catalogue is in preparation. Inquiries should be addressed to the general secretary, I.S.T.D., 17, Manchester Street, W.1, who will be pleased to send application forms and further particulars.

Dr. Andrew McNae Wyllie, deputy physician-superintendent of the Crichton Royal Institution, Dumfries, has been appointed physician-superintendent of Aberdeen Royal Mental Hospital in succession to Dr. R. Dods Brown, who is retiring on Sept. 30.

Some medical journals in Italy have temporarily suspended publication, the *Rivista de Neurologia* among others.

Sir Arthur Newsholme, K.C.B., who died on May 17, bequeathed the residue of his estate to the London School of Hygiene and Tropical Medicine.

The Ministry of Health has set up an informal committee, of which the Ministry of Supply, the Ministry of Works, and the Radium Commission are represented, whose work it will be to see that the best use is made of the limited supplies of deep-x-ray apparatus. Hospitals placing orders for such equipment should send copies to the Supplies Division, Ministry of Health, Whitehall, London, S.W.1.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Alliologie Westcott*, London; SECRETARY, *Medicorum Westcott*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Black Hairy Tongue

Q.—What are the aetiology and treatment of black hairy tongue? This condition has arisen quite suddenly in my patient, an old man who has had a stroke within the last year, and who is a chronic asthmatic. He smokes one ounce of tobacco a week.

A.—The hairy appearance is due to overgrowth of the filiform papillae on the centre of the dorsum of the tongue. There is an inflammatory reaction in the papillary layer of the corium. The black colour is usually thought to be due to a fungus, the *Aspergillus niger*, whose spores are black. In some cases a yeast has been isolated, or bacteria producing black colonies; in others the black appearance is due to food debris, or the papillae may darken with age. Other causes which have been suggested include tobacco smoke, irritant mouth-washes, sulphonamide drugs, gastric hyperacidity, or a trophoneurosis. It is not due to nicotinic acid deficiency, which causes black tongue in dogs. Although the patient is apt to worry about the appearance of his tongue, it usually produces no ill effects unless the overgrown papillae touch the soft palate and cause retching. Malignant changes do not occur. The condition may disappear spontaneously, but treatment is not likely to prove efficacious. Attention should be paid to oral and dental hygiene, and the tongue may be gently scraped daily. A mild mouth-wash, such as sod. bicarb. gr. 10 to 1 oz. of water, may be used twice daily. The patient should not smoke. The application of thymol (1 in 1,000 solution) has been recommended for cases due to a fungus.

Types of Pertussis Vaccine

Q.—I wish my child, aged 5 years, to have prophylactic inoculations against whooping-cough. I notice that some firms make up two types of material—one of which is labelled "Fort." Could you tell me the best type to use?

A.—To get a reasonable degree of protection against pertussis (whooping-cough) it is essential to use large doses of a smooth-phase vaccine. American workers have recommended a total of 80,000 to 100,000 million organisms given in 1.0, 2.0, 2.0, and 3.0 c.c.m. doses at weekly intervals of a vaccine containing 10,000 million organisms per c.c.m. This method has obvious administrative difficulties, and recent work by Bell (see under "Any Questions?", *British Medical Journal*, 1941, I, 622) has shown that two 1-c.c.m. injections of an alum-precipitated vaccine (10,000 million organisms per c.c.m.) at a month's interval gave as good results as the larger dosage more frequently. Pending the preparation of A.P. vaccine in this country, a useful compromise is three injections of 1.0, 1.0, and 2.0 c.c.m. of a (10,000- or 20,000-million-organisms-per-c.c.m.) vaccine (this is the "Fort" vaccine) with a week's interval between the first and second injections and a month between the second and third.

Quinine Resistance in Malaria

Q.—One hears frequent mention these days of the danger of inadequate doses of the sulphonamides, resulting in a sulphonamide-resistant strain of, say, streptococci or gonococci. What chances are there of breeding a quinine-resistant malaria parasite by the common custom of taking 5 gr. of quinine daily for prophylactic purposes? In these days of quinine shortage it is an important consideration.

A.—Some strains of malaria parasites have been shown to be naturally more resistant to quinine than others. Whether a strain can be made resistant through administration of quinine is much more debatable. Strains of trypanosomes made arsenic-resistant by minimal doses of trypanocidal arsenical compounds are well known, and it has recently been shown that the monkey malaria parasite, *P. knowlesi*, can be made resistant to plasmoquin in this way. Theoretically, therefore, it cannot be denied that quinine-

resistant strains of the malaria parasite might result through the taking of small doses of quinine, and some authors have even described such a condition. The general feeling, however, among authorities is that the occurrence of quinine-resistant parasites brought about in such a manner has not been satisfactorily established, and were it a common result such an effect would almost certainly by now have been clearly demonstrated. Cases suspected to be resistant to quinine are occasionally seen in hospital practice, but careful inquiry usually shows that the patient has not had the quinine he is supposed to have had, and the case usually clears up at once when the observer himself sees an adequate dose administered in his presence. In this connexion, of course, malingering may enter in. Briefly the occurrence of quinine-resistant malaria parasites brought about as a result of regular daily dosage of prophylactic (suppressive) quinine treatment may be ruled out as unsupported by any satisfactory evidence and as entirely contrary to general experience.

Lip-reading for the Deaf

Q.—How is lip-reading taught and learned? Would it be feasible for a G.P. to help a boy of 18 with deafness due to bilateral chronic otitis media to learn to lip-read? The boy wishes to go to the university.

A.—Lip-reading is usually taught by a special instructor who has been trained as a lip-reading teacher. Any local association or institute for the deaf would no doubt be able to give the name and address of a suitable instructor in lip-reading. It is assumed that the patient could be treated privately. If not, it will be necessary to secure his admission to one of the institutes for the deaf. It will be rather a waste of a qualified medical practitioner's time to undertake such tuition himself. An intelligent boy of 18 should do quite well and should learn to lip-read sufficiently well to enable him to go to a university. This has been possible in cases within the writer's experience. One Army cadet, for instance, who became completely deaf as a result of meningococcal meningitis during the last war became so proficient in lip-reading as to proceed to one of the well-known universities and become a lecturer in a scientific subject—a position he still holds.

Hair Pigments and Greying

Q.—In the *JOURNAL* of July 24, p. 140, you published a question and answer on the greying of hair. I shall be grateful for information on the following points: (1) What are the pigments which produce the colours of human hair? (2) How are these pigments elaborated? (3) From what foods? (4) Do iron, copper, and manganese produce these pigments? (5) Is greying a failure to metabolize these pigments, or is it a failure of the hair to receive the pigment? (6) Would a prophylactic minimal dose of iron, copper, etc., help to supply hair pigment—either by supplying substances lacking in food or by preventing over-destruction of pigment substances?

A.—Very little is known about the colour of human hair. It is probably due to varying amounts of the pigment melanin and the way in which the pigment is deposited—e.g., granular as in black hair or diffuse as in red hair. Melanin is a complex black pigment formed from tyrosine, catechol, or related substances by oxidizing enzymes. The origin of the melanin in hair has not been established. The melanin of pigmented skin is assumed to be formed from tyrosine.

The greying of hair is ascribed to the absence of melanin, presumably due to failure of melanin formation. Prevention of premature greying of hair by treatment with vitamin B preparations, β -aminobenzoic acid, and endocrines has been dealt with in the answer to a question in the *Journal* of July 24, p. 140. The white hair of old age is due to an increased proportion of calcium carbonate and phosphate. These substances form about one-third of the ash of white, compared with one-sixth to one-fifth in coloured and grey hairs.

It cannot be stated that any particular foods contribute to pigment formation in hair. The melanin is presumably formed ultimately from some breakdown product of protein, but the amount is small and negligible compared with the total daily intake of protein. There is no evidence that iron, copper, and manganese influence hair pigments.

A Difficult Skin Case

Q.—A man, aged 47, six years ago (in Nairobi) first noticed his left foot getting hot while playing golf. After the game the left foot used to get a blister. The disease has been progressive. The hands start swelling now, and both feet get blisters after walking. He has had to give up police work as he is unable to walk. At present his hands and feet feel hot, tingling, and sticky due to slight moisture. The taking of a meal or immersion of the hands in cold water leads to a diminution in the swelling for a short period.

A.—It is very difficult to offer a diagnosis with the information given of this very chronic case. We presume that the usual tests (urine, Kahn, and blood count) have been made. In every case of

bullous or vesicular eruption of the extremities, especially of the feet, the first step is to exclude epidermophytosis, which may trouble a patient for years. Special attention should be paid to the interdigital clefts, particularly that between the fourth and fifth toes, and also to the nails. It is now well recognized that a more generalized eruption, an epidermophytide, affecting the hands as well as the feet, may occur and is cured only when the foot trouble has been cleared. It would be well to take care that footwear has been freed from possible infection.

Assuming that epidermophytosis can be excluded, pompholyx (acropompholyx) vera must be considered. This apparently may be constitutional, or of climatic or nervous origin. The best remedy would be change of climate, especially as the patient may not have had his usual leave owing to war. The diet should be simple, alcohol should be avoided and also highly seasoned foods. The itching may be relieved by 1/4 gr. luminal twice a day; locally by soaking the feet in weak potassium permanganate followed by dusting with a drying powder such as the following: alum 5 parts, tannic acid 5 parts, boric acid 10 parts, talc to 100 parts.

There are other possibilities, such as disturbance of salt metabolism by heat, but this is not likely if the patient has been resident in the Kenya highlands.

Oestrogens for Small Breasts

Q.—On p. 125 of the issue of July 24 there is an answer to a question about oestrogens for small breasts. You recommend using preparations which contain 2 mg. per g. Would you kindly let me know from whom such a preparation could be obtained, and if possible how often it should be applied, and for how long? Also, what is the maximum period that such a preparation could be persevered with if there is no response?

A.—It should be pointed out that the answer to the question on oestrogens for small breasts did not recommend the use of this hormone except where there are other general signs of ovarian deficiency. It is not the function of this column to supply information concerning the various commercial preparations of hormones or other drugs. Application should be made daily. In responsive cases signs of development of the mammary tissues are usually manifest within a month or two. If there is no response at the end of three months it is unlikely to appear subsequently. It should, however, be clearly realized that such treatment is purely substitutional, and that the artificially stimulated development will soon regress once therapy is discontinued. Finally, it must be emphasized that continued oestrogen therapy is undesirable and may be dangerous. For instance, it has been shown that chronic mastitis may be aggravated by oestrogen administration. If menstrual function is normal its rhythm may be disturbed by continued oestrogen therapy, the menstrual flow being sometimes suppressed, sometimes considerably increased in length and volume. The injections should therefore be applied during the first two or three weeks of the cycle only. In any case oestrogens should not be given continuously for more than 3 or 4 months without periods of remission. In view of the purely temporary effect obtained, and that only in cases showing other evidence of ovarian deficiency more obviously claiming therapeutic adjustment, it would seem that the administration of oestrogen for small breasts should be rarely called for.

Control of the Common Cold

Q.—In view of the fact that vaccines appear to be of little use in preventing the common cold, I should be glad to know what general measures should be adopted to prevent loss of time through colds among factory workers. I have been asked by my management whether the routine administration of vitamin supplements to the workers would increase their resistance to colds; also whether routine exposure to ultra-violet light during the winter months would be helpful. Is the voluntary or compulsory wearing of masks during the active stage of a cold likely to prevent spread of infection?

A.—With an estimated (American) average of three colds per person per year this apparently trivial infection must cause great economic loss through time off work due to the cold itself or its complications (sinusitis, bronchitis, pneumonia), and through impaired efficiency in those who carry on. Counteractive measures among factory workers should have two objectives: (1) to raise resistance to the common cold and its complications, and (2) to prevent the spread of infection among the employees. "Physical fitness and well-being does help the individual to resist 'catching cold,'" Locke, for instance, found that two-thirds of a group of persons whose physical fitness was rated on physiological tests as above a certain standard had only one cold each per year, whereas four-fifths of another group below this standard had four or more colds per year. An adequate and well-balanced diet, sensible clothing, in particular footwear, and the avoidance of fatigue or excesses, help to maintain physical fitness, and these facts should be known among factory workers. If there is evidence of vitamin deficiency in the diet, that must be made good, if necessary by synthetic

preparations. Many people claim that a daily dose of cod-liver oil throughout the winter helps to ward off the cold, but there is no evidence that excess of any particular vitamin will protect against the infection. The prophylactic value of ultra-violet irradiation is in doubt. Colebrook² failed to show any benefit, but Sherman³ found, in a comparative trial at the Bournville Works of ultra-violet light, vitamins A and D, and a mixed vaccine by injection or by mouth that the only prophylactic which was associated with a significant reduction in the incidence of colds, with a considerable saving in time lost, was ultra-violet light. Physical well-being will also lessen the risk of complications, particularly if management and patients alike agree that an individual with a cold should remain indoors preferably in bed, for 1 or 2 days during the acute stage.

Control of the spread of infection in the factory will be helped if the "colder" person is encouraged to report sick at once. Chronic sufferers from colds or their complications should be carefully examined and receive appropriate treatment. An environment arranged for maximum comfort is inimical to the spread of the common cold,⁴ so that air-conditioning should, wherever possible, be introduced. Alternatively, there must be good ventilation without draughts and with the atmospheric temperature maintained around 60° to 65° F. Measures must be taken to prevent and control the dissemination of dust. If colds are very prevalent, aerial disinfection by a bactericidal mist of sodium hypochlorite atomized by hand or by pressure pump may be used without risk, and perhaps with some benefit. The wearing of masks in the factory besides creating difficulties, is not likely to effect much, since there are ample opportunities for catching the infection elsewhere.

Infected Butter and Cheese

Q.—Is there any risk of milk-borne infections being conveyed by butter and cheese (and cream when available), especially to young children? If so, can any precautions be taken?

A.—Almost all butter sold in this country is made from pasteurized milk. Pasteurized milk is being used increasingly in the manufacture of cheese, but the danger from this product is small in any case since pathogenic bacteria, including tubercle bacilli, die out during the usual process of maturation. There is some risk of normal times from the consumption of raw cream, but it should be pointed out that pasteurized cream is a perfectly satisfactory product. A further reason against any serious disquiet on this score is the quantitative factor. No milk product is consumed in such quantities as milk itself, of which a child may receive a pint or more daily, in which the concentration of tubercle bacilli is sometimes such that the infective dose for a guinea-pig is only a small fraction of a c.c.m. Whether or no a serious tuberculous lesion is produced naturally depends in part on the magnitude of the infecting dose which from badly infected milk consumed over a long period may be very large. (The infectivity of butter and particularly of cheese was discussed in an annotation in the *Journal* of June 12, p. 71)

LETTERS, NOTES, ETC.

Research in Senile Disease

Prof. H. E. ROY writes: With reference to the article, "Possibilities of Research in Senile Diseases" (Aug. 21, p. 219), we have in Liverpool a research institute, one of the objects of which is to examine healthy persons over 35 years of age. This Institute of Research for the Prevention of Disease is administered by a committee of the Liverpool and District Hospital for Diseases of the Heart. Dr. I. Harris wished to undertake work on the prevention of high blood pressure and allied conditions, and he persuaded the committee of the Heart Hospital to establish a separate research institute. The research work consists of work on animals and the examination of healthy people. The idea of the latter procedure is to establish standards of health for older people, to detect the early and preliminary stages of departures from health, and to prevent further degenerations, if possible. It seems to me that this project is akin to that suggested by Mr. Creman. If funds were available, our activities could be enlarged after the war. Finally, I must point out that if anyone is found to be suffering from disease, that individual is referred to his or her own private practitioner.

"Sulphamethazine"

Imperial Chemical (Pharmaceuticals) Ltd. writes: In your issue of Aug. 21, p. 230, you published a paper "Pneumonia treated with Sulphamethazine." The authors are probably unaware that the correct name and description of this material has recently been changed to "sulphamezathine" brand of sulphadimethylpyrimidine.

TRANSFUSION REACTIONS AND FATALITIES CONSEQUENT ON CIRCULATORY OVERLOADING*

BY

R. DRUMMOND, M.R.C.S., L.R.C.P.

Late Assistant Lecturer in Pathology, Welsh National School of Medicine, Cardiff; Regional Transfusion Officer, Welsh Board of Health

Much research has recently been devoted to the identification of abnormal agglutinogens and iso-agglutinins. Noteworthy has been the discovery of the Rh factor by Landsteiner and Wiener (1940). Attention, too, has been focused on the grave danger of transfusion of incompatible blood. It is well known that death may follow transfusion of an incompatible agglutinin—e.g., B cells into an A recipient, etc. Yet recovery may follow such a mishap. Kilduffe and DeBailey (1942) give the mortality rate as about 50%. The total incidence of haemolytic reactions due to transfusion of incompatible cells over a large series of cases is very low. Thus Kilduffe and DeBailey in a collected series of 40,000 transfusions found 80 (0.18%) haemolytic shock reactions, of which 32 (0.07%) were fatal. The total number of deaths was 45. I have personally seen only two such cases in 10 years; both were fatal, and both were due to faulty blood grouping by the slide technique. However, as Wiener (1939) remarks, "it is fortunate that the transfusion of incompatible blood is not always fatal; indeed, in a number of instances the reactions were so mild or insidious that they passed unnoticed or were attributed to other causes." Serious reactions have followed transfusion of as small a quantity as 10 c.cm. of incompatible blood. In some cases death has been almost instantaneous.

According to Kilduffe and DeBailey, who cite Bordley, there is a definite relation between the amount injected and the mortality. Recoveries have been reported—e.g., two cases by Wiener *et al.* (1941)—and one of these was a Group O recipient who received Group B cells. A similar case was reported by Mollison and Young (1941).

Further, Wiener noted that second in importance to injection of blood of a wrong group as a cause of severe or fatal reactions to blood transfusions is the use of universal donor blood. He mentions that, according to Gesse (1935), the use of universal donor whole blood on recipients of groups other than O is apt to be followed by a haemolytic reaction if more than 200 c.cm. is transfused when the patient is suffering from severe anaemia, or if the serum of the donor is of high titre for the recipient's cells. However, while this is probably true of severely anaemic recipients of the A-B system, it is certainly not true of the ordinary run of casualties. The use of universal donor blood in recipients of all groups suffering from acute haemorrhage has been repeatedly proved to be safe and successful in thousands of casualties in the present war.

A Frequent Cause of Reactions

Due regard having been paid to deaths consequent upon agglutination and haemolysis either of donor's or of recipient's cells, there still remains in my opinion a more frequent cause

of reactions and fatalities. I refer to overloading of the circulation in the chronically anaemic and diseased subject.

In the Welsh Board of Health Regional Transfusion Service there is a mutual arrangement whereby all transfusions given in hospitals are notified on a standard record form. With the aid of these records it has been possible to track down and investigate some interesting transfusion reactions. It is noteworthy that in 2,300 transfusions notified in the last 2½ years there has not been a single instance of death due to transfusion of cells of an incompatible blood group. There have been some cases of death from pulmonary oedema and cardiac failure due to circulatory overloading in chronically anaemic subjects; also, there have been a few haemolytic reactions—e.g., jaundice or haemoglobinuria—following the use of Group O or of homologous blood.

Whitby (1941), in an address to the Shaftesbury Military Hospital Medical Society on transfusion for battle casualties, noted that these subjects contrasted with those commonly requiring transfusion in peacetime practice in that they had been previously healthy and had no cardiac disability; it was therefore safe to give at least two pints of blood or plasma quickly to anyone with a blood pressure consistently below 100 mm. Hg, and then to carry on with a slower drip transfusion. It is common knowledge that one problem which sometimes confronts a resuscitation officer when dealing with air-raid casualties is how to get the fluid in quickly enough. Indeed, positive pressure may have to be used, and it may be necessary to introduce a pint of plasma or blood in 15 minutes.

The reason why no cardiac embarrassment occurs in Service casualties is, of course, simple. First, the introduced fluid replaces lost fluid. Secondly, the myocardium is invariably normal and therefore functions efficiently. It is well known in clinical medicine that it is impossible to strain a normal heart. This has been abundantly proved experimentally. I quote here from Starling (1930):

"Experimentally it is found that the isolated heart has a marvellous power of adaptation—i.e., regulating its activity according to the mechanical demands which are made upon it. Thus if we keep the venous inflow constant it makes no difference to the output of the heart whether the average arterial pressure be maintained at 80 or 160 mm. Hg, although in the latter case the heart must do twice as much work in order to keep the outflow at the same level. Again, if we maintain the arterial pressure constant and alter the venous inflow, we find that within very wide limits the heart is able to expel against the arterial resistance the whole of the blood which flows into it from the veins. In this way we can alter the output of a small heart weighing 50 grammes from 300 to 3,000 c.cm. per minute."

Further, Hayward (1942) showed that even in only reasonably healthy subjects serum or plasma could be introduced fairly rapidly. He transfused 50 subjects suffering from chronic arterial disease each with 800 c.cm. of pooled serum, the fluid being introduced at a rate of 5 to 15 c.cm. a minute. The incidence of rigors was 30%. If the serum was injected slowly the cardiovascular system adjusted itself to the increased blood volume readily, there being no increase of venous pressure, and the blood pressure in most cases showed no significant change.

* A paper read at a meeting of Regional Transfusion Officers held at Leeds on March 4, 1943.

Overloading after Rapid I.V. Injections

Sharpey-Schafer and Wallace (1942) investigated the question of circulatory overloading following rapid intravenous injections. They used subjects without cardiovascular disease, and up to 2,000 c.cm. of saline, serum, or blood was injected at rates of from 54 c.cm. to 168 c.cm. a minute. The venous pressure was raised up to 11 cm. H₂O when there was considerable retention of injected fluid in the circulation, as indicated by the fall in the Hb. Radiographs showed an increase in the diastolic size of the heart, enlargement of pulmonary arteries, and prominence of the vascular markings in the lung fields. Vital capacity was diminished, but there was no pulmonary oedema. Despite rise of venous pressure many subjects had no increase in heart rate. However, 4 out of 12 had electrocardiographic signs of heart stress. There were no important symptoms. Those authors stated: "There is evidence that the peripheral and pulmonary capillaries and veins dilate to accommodate the increased blood volume." Lastly, Kilduffe and DeBakey mention that they have infused 650 c.cm. of blood in three minutes! They point out that when myocardial disease is present transfusions must be given with caution; but, apart from this, the suggestion of the danger of embarrassing and overloading the cardiovascular system by rapid transfusion has no rational basis, and they therefore rightly condemn the term "speed shock."

It is apparent, therefore, that, if the myocardium is normal and is functioning efficiently, there is nothing to be feared from rapid transfusion or from overloading the circulation.

Risks of Transfusion in Anaemia

The position is, however, quite otherwise when the functional efficiency of the myocardium has been affected by long-standing anaemia or severe toxæmia. Very grave risk indeed may attend the rapid transfusion of the chronically ill and severely anaemic subject. The risk seems to be particularly grave in pernicious or aplastic anaemia, in severe anaemia consequent on chronic and oft-repeated haemorrhage—e.g., of uterine or gastric origin—in malignant disease associated with cachexia and haemorrhage, and in puerperal cases associated with the effects not only of much haemorrhage but also of sepsis.

Plummer (1936) reported five deaths from heart failure after transfusion in chronically anaemic subjects. Careful preliminary tests were performed and there was no incompatibility. Death occurred, often with pulmonary oedema but without evidence of haemolysis, from 30 minutes to 19 hours after transfusion. It was noted that few such cases had been reported; but this was not a true index of their incidence, for these cases were seen in a two-and-a-half-year period at one hospital. They were typical examples of the danger of rapid transfusion or circulatory overloading in subjects with enfeebled cardiac action due to long-standing anaemia. One case well illustrated the very grave danger of transfusion when circulatory failure was already present.

According to Riddell (1939) the commonest cause of a fatality following blood transfusion is circulatory failure. It may be due to overloading of the circulation or it may be secondary to a rigor. Whitby (1942) has pointed out that "too fast a rate can cause a rigor, which ceases instantly if the rate is slowed." As Riddell rightly contends, if the blood volume is normal—i.e., not depleted by haemorrhage—the production or not of circulatory failure after the intravenous infusion of fluid will depend on three factors—namely, the volume of blood introduced, the rate of its introduction, and the mechanical efficiency of the myocardium at the time. Marriott and Kekwick (1940), in their admirable paper on rate and volume of transfusion of blood in anaemia, laid down four important cardinal principles for the transfusion of severely anaemic subjects. These are: (i) rate not to exceed 1 c.cm. per lb. of body weight per hour; (ii) if the Hb is 25% or less, and if there is cachexia or cardiac or respiratory disease, the rate should not exceed 0.5 c.cm. per lb. of body weight per hour; (iii) maintain steadily the determined rate of transfusion and do not accelerate for short periods; (iv) watch carefully for signs of heart failure (dyspnoea, cough, basal rales) and suspend transfusion if they appear. They

consider that the giving of a pint in half an hour is irritating and unsatisfactory. All too often these important principles are neglected.

Too Rapid Transfusion in the Anaemic

The following cases illustrate the dangers of too rapid transfusion in the severely anaemic and chronically ill subject.

Case 1.—A man aged 54 was admitted to hospital suffering from chronic anaemia and cachexia due to carcinoma of the stomach. He weighed about 10 st. and had lost some 3 st. in weight. The Hb was 50% and the blood group was O. Transfusion of 10 c.cm. Group O whole blood was given in 30 minutes. He then experienced severe pain in the chest and headache. He had a moderate rig which lasted about half an hour, and was left with a feeling of tightness in the chest. The transfusion was stopped. Next day he still complained of tightness in the chest, and rhonchi were audible in both lungs. He recovered. Careful cross-matching test after the transfusion showed no incompatibility. The patient died 16 days later of unrelated causes. There was no necropsy.

Comment.—If one works on the principles laid down by Marriott and Kekwick—i.e., 1 c.cm. per lb. of body weight per hour—this patient should have received 140 c.cm. in an hour, or 70 c.cm. in half an hour. In fact, he received 280 c.cm. in half an hour—i.e., the transfusion was given at four times the rate it should have been given.

Case 2.—A multipara aged 39 was admitted urgently for treatment of profound secondary anaemia. The patient stated that she had had a miscarriage, had advanced in pregnancy seven months, and that she had been bleeding per vaginam for 19 days. However, her doctor subsequently affirmed that, so far as he could ascertain, bleeding had gone on intermittently for several weeks. The blood pressure was 150/80 on admission, the Hb 25%, and the blood group A. The next afternoon a transfusion of Group A whole blood was given. Full cross-matching tests were carried out by an experienced pathologist and there was no incompatibility. The patient had not previously had a transfusion. Four oz. was infused in 10 minutes, when the patient complained of a sense of constriction in the chest, severe precordial pain, and a sense of coldness, which in a minute or so was followed by a rigor lasting a few minutes. Slight cyanosis of the lips was noted. The transfusion was discontinued. An hour later her condition had deteriorated very much; she was semi-comatose, had slight cyanosis of the lips, and the pulse was rapid and feeble. Some 24 hours later the condition seemed to have improved, and it was decided to try the effect of a further transfusion. A second bottle of Group A blood was used. Cross-matching tests showed complete compatibility. In the next two hours a further 8 oz. of blood was given. Some 44 hours after starting the first transfusion the patient died of circulatory failure. **Necropsy:**—Weight of body about 10 st.; nourishment good. There was profound anaemia of all organs except the lungs and liver which were congested. The lung bases were oedematous; the kidneys normal. The uterus was 5 in. long and contained placental fragments. There was no evidence of intravascular haemolysis.

Comment.—In this case the rate of transfusion was too rapid. The determined rate of transfusion, since the Hb was only 25%, should have been 0.5 c.cm. per lb. of body weight per hour. Thus from the first bottle 114 c.cm. was given in 10 minutes, whereas the rate should have been 70 c.cm. in 60 minutes. The rate of introduction of the blood was about 11 c.cm. a minute, whereas it should have been about 1.5 c.cm. a minute.

Case 3.—A 36-year-old woman had suffered from symptoms of dyspepsia and epigastric pain after meals for two years. Symptoms had become worse in the last four months. Three days before admission she had a very severe haematemesis. It is not known whether she had suffered from melæna or haematemesis previous to this. She was sent into hospital urgently and was found to be profoundly anaemic and weak. The blood count showed 1,600,000 red cells and 22% Hb. She was at once given a transfusion of stored Group O whole blood. The recipient's group was not known, but a cross-matching test between the recipient's serum and the donor's cells showed compatibility. In barely 30 minutes the patient was given 540 c.cm. of blood. Transfusion had proceeded when she had a rigor. Her general condition had deteriorated, respirations became faint and rapid, and 14 hours after the cessation of transfusion she was comatose. After a further 5 hours the patient was still comatose and had what seemed to be a slight convulsion. Death occurred 54 hours after the end of transfusion. There was no necropsy.

Comment.—The weight of this patient was estimated to be about 9 st. If this is so, and with a Hb of 22%, the rate of

transfusion should have been 0.5 c.cm. per lb. of body weight per hour—i.e., about 70 c.cm. in one hour instead of 540 c.cm. in half an hour.

Cases of Too Large a Transfusion

The next two cases concern the question of overloading the circulation by the factor of transfusion of too great a volume of fluid.

Case 4.—A woman aged 24 was suffering from severe chronic anaemia (pernicious?), albuminuria, and oedema of pregnancy. The haemoglobin was 22%. A radiograph revealed a much-dilated heart (see Fig.). A transfusion of concentrated red cells,* from

Radiograph showing the severe cardiac dilatation in Case 4.

2 pints of whole blood, was given with especial care at a very slow drip rate after careful cross-matching. Both donor and recipient belonged to Group A. After six hours about 400 c.cm. had been given when the patient complained of a sensation of constriction in the chest and developed a slight irritative cough. The ward sister had been warned to look out for these symptoms, and the transfusion was promptly stopped. The symptoms immediately ceased and there was no ill effect afterwards. The recipient, who was Rh-positive, was much improved.

Comment.—This case supports the opinion that in cases of severe chronic anaemia it is better to give initially repeated small transfusions of about 250 c.cm. than single large-volume transfusions. I think, too, that concentrated red cells should be used in preference to whole blood, so that the maximum number of cells may be given in the minimum volume of fluid.

Case 5.—A man aged 40 was admitted to hospital suffering from severe injuries to the left leg and right ankle. It is not evident that there had been extensive loss of blood. The patient was somewhat shocked. No regular blood-pressure recordings were made, and in the space of two or three hours he received 5 pints of Group O whole blood. The blood group of the recipient is not known. All the donors' blood had been carefully checked and grouped on both agglutininogen and agglutinins by the issuing blood store. It is stated that the transfusion was persevered with because the pulse rate continued to rise. The left leg was amputated above the knee a couple of hours later. The patient died shortly after operation. **Necropsy.**—The body was well nourished and showed rigor mortis. The right auricle of the heart was tremendously distended and ballooned. So great was this distension that the heart-muscle fibres were separated from each other, rendering the wall of the right auricle semi-transparent. The right auricular appendage was grossly distended. A small agonal thrombus was present in the main branch of the right pulmonary artery. The lungs were extremely oedematous, and there was a little aspirated food in the bronchi. The endothelium of arteries and veins showed intense haemoglobin staining. **Histology.**—Right kidney: There was autolysis of the kidney parenchyma. In one area a very small amount of yellowish pigment was seen in the tubules of the medulla. Left kidney: Some of the vessels showed lysis of red corpuscles and the presence of numerous bacilli. In other vessels there was much brown pigment consisting of coarse granules arranged in clumps. The lungs showed oedema, and the blood in all vessels appeared to be haemolysed. There was fat embolism of the lungs, but of only moderate degree.

* All the plasma was siphoned off and half its volume replaced with citrate solution.

Comment.—This case illustrates well the grave dangers of uncontrolled resuscitation—i.e., no careful blood-pressure recordings, etc. There can be no doubt that too great a volume of blood was transfused. The essential cause of heart failure was circulatory overloading due to the introduction of too great a volume of blood. The haemolysis was shown to be a post-mortem phenomenon.

Indiscriminate use of universal donor blood is to be deprecated. Compatibility tests ought always to be performed in routine hospital practice, and homologous blood given if it is desired to raise the haemoglobin level. If facilities for tests are not available, then the services of the nearest blood depot should be utilized. In emergencies—e.g., wound shock and haemorrhage—it is safer and wiser to use serum or plasma in order to achieve the object in view—namely, restoration of blood volume—and in the interim full cross-matching tests may be carried out should whole blood be necessary.

Discussion

A case very similar to that just quoted was described by Tubbs (1942). His patient, a 46-year-old man, suffered from chronic lung abscess. During lobectomy there was moderate blood-loss. One pint of saline and 3½ pints of blood were given. After operation his condition was excellent, but on being returned to bed he became cyanosed, pulmonary oedema set in, and thin watery blood-stained fluid accumulated in the air passages. Death occurred two hours after operation. At necropsy the right side of the heart was bloated with blood, and the lungs and air passages were filled with great quantities of blood-tinged oedema fluid. As Tubbs points out, the myocardium of this man was not normal, but had been subjected to the chronic toxic effects of a lung abscess for 12 months. Under such conditions the danger of rapid intravenous injections was only too real. Incidentally A. S. and H. G. Grünbaum (1911), in a forthright article on "post-operative drowning," long ago warned of the grave danger of post-infusional death after intravenous saline injections in cases of surgical collapse. It is evident that this warning needs repetition at the present time.

While the most important cause of transfusion reactions or fatalities is the injection of incompatible blood, it nevertheless seems certain that a common cause of such mishaps is overloading of the circulation. I believe that this remark applies especially when universal donor whole blood is used on anaemic recipients of the A-B system. Not only is there grave danger in overloading the circulation in such cases, but if in addition to this a reaction occurs between the donor's agglutinins and the recipient's cells, then a condition of "haemolytic shock" may be set up. This condition of haemolytic shock in association with a sudden overloading of the circulation from too rapid transfusion may well prove too great a strain on the weakened anaemic myocardium, and circulatory failure may ensue, with fatal result. It should be borne in mind that in severe chronic anaemia the functional capacity of the heart may be seriously impaired and its powers of reserve negligible. The cavities are often much dilated, and the capacity to undergo further compensatory dilatation may be so grossly diminished that the heart becomes unable to accommodate a given volume of blood if too rapidly introduced. Starling has pointed out that an increased diastolic volume means greater length of the muscle fibres of the heart wall. As with voluntary muscle fibres, the energy of contraction is a function of the length of the muscle fibres—a generalization known as "Starling's law of the heart." But in the chronically anaemic myocardium dilatation may be present, possibly of considerable degree (see Fig.). Clearly, under such conditions the heart fibres, already stretched and not contracting to their fullest extent, have little capacity to stretch further. Consequently the right auricle becomes unable to accommodate a large volume of blood suddenly introduced, and fails to expel its contents fully. Failure then ensues. The extra volume of blood must become accommodated somewhere, and, as Sharpey-Schafer has shown, this is done in the vessels of the lungs. Hence the earliest signs of overloading are crepitations due to pulmonary oedema. The precordial pain of which these patients so often complain is presumably due to overdilatation of the right auricle and tension on the

pericardial sac. At necropsy fatal cases constantly show cardiac dilatation and pulmonary oedema and congestion. The pulmonary oedema is evidence of left-sided heart failure.

Treatment should comprise prompt cessation of transfusion, the administration of oxygen, and the injection of morphine and atropine. Adrenaline is contraindicated. Venesection may be necessary to relieve the load on the right heart.

A reasonable rate of transfusion in severe chronic anaemias is 40 drops a minute, and the giving of one pint of whole blood should be spread over at least three hours if disasters from circulatory overloading are to be avoided.

I desire to express my thanks to Prof. J. B. Duguid and Dr. J. Gough, of the Department of Pathology, Welsh National School of Medicine, Cardiff, for help and criticism in the preparation of this paper; to Prof. M. Stewart of Leeds, who kindly drew my attention to the Grünbaums' paper; and to Dr. L. Proger of the M.R.C. Serum Drying Unit, Cambridge.

EFFECT ON THE UTERUS OF EXTRACTS OF GORSE (ULEX GALLI)

BY

WILSON SMITH, M.D.

AND

ANDREW WILSON, Ph.D., M.B.

(From the Departments of Bacteriology and of Pharmacology, University of Sheffield)

In parts of Yorkshire and Derbyshire infusion of gorse is a traditional remedy for retained placenta in the cow. An apparently successful demonstration of its efficacy aroused our curiosity and led us to test its effect upon isolated strips of guinea-pig uterus. Sustained tonic contraction was consistently produced by addition of the watery extract to the fluid in which the uterus was suspended. The consequent investigation was designed to isolate the active principle and to determine its chief pharmacological actions. These objects have not yet been achieved, but we think that the results obtained so far should be published.

Preparation of Extracts

Terminal shoots of gorse from several bushes were passed through a farm hay-chopper and then through a hand tissue-grinder to give a coarse powder. Aqueous extracts, prepared by boiling the minced gorse in water, N/100 HCl, or phosphate buffer solution pH 8.4, were found to be of approximately equal potency when tested on isolated guinea-pig uterus, whereas direct extraction of the gorse with a number of organic solvents failed to yield active products. During attempts to isolate an active principle from the infusions many potent fractions of varying degrees of purity were obtained, but inexplicable irregularities decided us to carry out pharmacological tests on a stock pool of concentrated extracts prepared by the following method, which gives consistently reproducible results and eliminates a considerable amount of inert material.

250 g. of minced tissue are boiled gently for half an hour in 2.5 litres of distilled water. The infusion is strained through muslin and then filtered through a layer of kieselguhr. Approximately 1,800 ml. of clear greenish-brown filtrate with a characteristic odour and acid to methyl red are obtained. Saturated solution of basic lead acetate is added until there is no further precipitation. The

voluminous precipitate is filtered off through kieselguhr and discarded. The filtrate, after removal of lead as lead sulphide, reduced to about 1/50 volume by distillation at 60–65° C. under reduced pressure. To this concentrate 9 volumes of absolute alcohol are added. A flocculent precipitate forms almost immediately, which is filtered off and discarded. The alcohol is removed from filtrate by distillation at 60–65° C. under reduced pressure; leaves a brown viscous fluid together with gummy material adhering to the sides of the distillation flask. The gummy material goes readily into solution in distilled water, and the flask washings used to make up the total volume to exactly 1/50 volume of original infusion filtrate.

Several batches of gorse extracted in this way yielded concentrates of indistinguishable potency; they were therefore pooled to give the stock concentrate referred to hereafter as "S."

The concentrate, when freshly prepared and still warm, has a characteristic pungent odour which is lost to some extent on storage. It is a clear golden-brown viscous fluid and acid to methyl red. Alkalization with NaOH causes deepening of the colour.

Pharmacological Actions

Technique.—In all tests on isolated tissues duplicate preparations were suspended in either Ringer's or Van Dyke's solution, capacity of each bath being 20 ml. One-ml. quantities of various dilutions of neutralized extract were used, and the concentrations recorded were calculated on the assumption that a further dilution of 1 in 20 was effected by mixture with the bath fluid. The period of observation was two minutes, but effects over long periods were also frequently studied. The tests on intact cats were made under nembutal anaesthesia, the uterus being kept submerged in Ringer's solution in the abdominal cavity.

Isolated Guinea-pig Uterus.—With the virgin uterus, S 1 in 1, invariably causes an immediate tonic contraction, sustained for least two minutes. The degree of contraction, shape of the contraction curve, and duration of effect depend not only upon concentration of extract but also upon the phase of the oestrus cycle. Uterus from a guinea-pig in oestrus is more sensitive than uterus removed at other periods of the cycle. Consequently we have found it advantageous to keep a number of spayed animals and to induce oestrus, as required, by inoculations of stilboestrol. With such sensitized preparations concentrations of 1 in 2,000 even 1 in 10,000 S may produce contraction; concentrations 1 in 500 or 1 in 200 cause maximal contraction, sustained for more than 20 minutes and without the step-ladder effect produced by smaller doses. Washing out the bath is always followed by a return of the normal tone and rhythmical contractions of the muscle. Uteri of pregnant guinea-pigs respond in the same way as those from virgin animals, but may be either more or less sensitive. The differences probably depend upon the period of gestation; they may be related to hormonal balance, but the data so far available are not sufficient to correlate these factors. Experiments on parturient uteri give results in striking contrast: the extract produces

FIG. 1.—Effect of S on guinea-pig uterus. A, Oestrus induced; sustained contraction. B, Parturient; contraction followed by relaxation.

only a small contraction of short duration, which is followed by prolonged abolition of uterine tone. No fewer than 64 guinea-pig tests have been made, with perfectly consistent results except in one or two cases in which the uteri were of such low sensitivity that effects were negligible. The effect of the extract on guinea-pig uterus is not influenced by previous addition of atropine to the bath, nor does the extract modify the response obtained with adrenalin. Typical experiments are illustrated in Fig. 1.

Effects on Uterus and Blood Pressure of the Cat.—A single experiment on the isolated uterus of the virgin cat indicated that it responds like the virgin guinea-pig uterus. In the intact cat intravenous inoculation of 0.2 ml. of S produces tonic contraction almost immediately, which is sustained for several minutes. There is an immediate transient fall of blood pressure, followed by a sustained rise. Further inoculations of extract after uterine tone and blood pressure have returned to normal reproduce the primary effects. It is probable that the transient fall of blood pressure is due to impurities, because some of our more highly purified fractions, which gave typical uterine responses, caused only the sustained rise of blood pressure. We have not had the opportunity of making tests on pregnant or parturient cats. Fig. 2 illustrates these effects.

FIG. 2.—Effect of S on intact virgin cat. A, Uterus; B, Blood pressure.

Isolated Human Uterus.—Preparations from 12 human uteri have been tested. In each case a piece of the upper segment was obtained at operation and transported immediately on ice to the laboratory. Two of the specimens were pregnant uteri about a week before full term from cases requiring upper-segment Caesarean section. In seven of the remaining cases the stage of the menstrual cycle was known—five were post-ovulation and two pre-ovulation. The

FIG. 3.—Effect of S on isolated human uterus. A, Pregnant uterus one week from term; B, Non-pregnant uterus pre-ovulation.

other three were cases of menorrhagia (2) and uterine sarcoma. All the patients were parous women. The effects of S on pregnant and non-pregnant uteri were in sharp contrast. With the former a 1 in 60 concentration of the extract caused vigorous sustained contraction, with retention of rhythmical tone and without any subsequent stage of relaxation. With the latter the same con-

centration produced an initial contraction of short duration followed by inhibition of tone and sometimes definite relaxation. Relaxation, when it occurred, was prolonged for at least six minutes; in some experiments the effect was maintained for 14 minutes, this being the maximum period of observation. Normal tone with small rhythmical contractions was regained when the bath was washed out. Different uteri varied in sensitivity, some being responsive to much lower concentrations than 1 in 60. The two pre-ovulation specimens were more sensitive than the others, and both showed definite relaxation. With pregnant uterus the addition of the extract after the induction of contraction with posterior pituitary extract caused no relaxation and, as in the case of guinea-pig uterus, its specific effect was not influenced by the previous administration of atropine. Fig. 3 shows the results of experiments with both pregnant and non-pregnant uteri.

Isolated Uteri of Other Species.—Tests with other species have been carried out as opportunity occurred. With a non-pregnant cow uterus, of which the stage of oestrous cycle and the parturition history were unknown, no significant response could be obtained, but with a pregnant uterus removed about a week before full term S 1 in 1,000 produced contraction comparable to that given by pregnant human uterus. Results with the rabbit have been less regular than with other species. Occasionally relaxation and abolition of tone have followed addition of extract, and even a 1 in 20 concentration of S caused only slight contraction in the uterus of a spayed animal. On the other hand, a 1 in 200 concentration produced vigorous and sustained contraction in the other uterine horn of the same animal, removed after oestrus had been induced. Only a single experiment has been made with dog uterus; it responded like guinea-pig uterus, but required much higher concentrations of extract to produce the contraction.

Isolated Guinea-pig Intestine.—Extract S may cause tonic contraction of guinea-pig intestine, but specimens vary widely in sensitivity. Our results suggest that the intestine is much less sensitive than guinea-pig uterus, especially when the latter is in oestrus.

Toxicity Tests

Only preliminary tests on mice have been made. With all routes of inoculation except intranasal, doses have been given in a volume of 0.5 ml.; intranasal inoculations were 0.05 ml. Subcutaneously 0.5 ml. of S (≈ 3.5 g. gorse approx.) causes no observable effects. By intraperitoneal inoculation the same dose kills mice within a few minutes, while 0.1 ml. and 0.05 ml. cause temporary distress with laboured respiration, followed by recovery. Intravenously 0.05 ml. kills within a few minutes, the animals dying in convulsions; 0.025 ml. causes temporary distress; 0.0125 ml. is without observable effect. The administration of 0.05 ml. intranasally under ether anaesthesia is followed by gasping respiration lasting for about half an hour, after which the mice recover and thereafter seem none the worse. The clinical symptoms suggest that toxic doses cause spasm of the bronchioles. Tests by oral administration and by the use of more highly purified extracts have not yet been made.

Methods of Further Purification of Extracts

While attempts to isolate the active principle have so far been unsuccessful they have indicated methods by which further purification may be achieved. Following the precipitations with basic lead acetate and alcohol, a further small amount of impurity may be precipitated out with 9 volumes of acetone. It is clear, therefore, that the active substance is soluble in both 90% alcohol and 90% acetone.

After treatment with lead acetate the addition of a saturated solution of mercuric acetate throws down a precipitate containing the activity from which purified extracts may be obtained. It is probable that the active principle is carried down by adsorption on inert material, for attempts to use mercuric acetate as a specific precipitant on more highly purified preparations were unsuccessful.

The active principle is soluble to some extent in ether, but the optimum conditions for ether extraction from watery solution have not yet been determined, so that very irregular results have been obtained. The most potent fractions produced so far have been obtained by prolonged ether extraction of concentrate S brought to pH 10 with NaOH, in a Kutscher and Steudel (1903) extraction apparatus. Subsequent removal of the ether by distillation leaves a pungent dark-brown oily material which goes completely into solution in distilled water. This aqueous solution is almost colourless and is distinctly acid to methyl red. Similar extractions with amyl alcohol and

petroleum ether failed to yield any active products. Extraction of the dry gorse with organic solvents is at present being investigated.

Discussion

This preliminary investigation indicates that *Ulex gallii* contains at least one active principle with pharmacological activity, chiefly on the uterus, in several species, thus affording some rational basis for its empirical use in farmyard obstetrics. The definite effects of extracts upon isolated human uterus suggest a possible extension to human obstetrics, but further work on chemical fractionation and purification is desirable before clinical tests are made, because there are some indications that the extracts thus far obtained may contain more than one pharmacologically active substance. From the common gorse, *Ulex europaeus*, Clemo and Raper (1935) isolated anagryrine and another crystalline base, but no pharmacological tests appear to have been made on them. There is, of course, no present indication that the active substance is an alkaloid, but its extraction with ether from alkaline aqueous solution suggests that it is a base, the acidity of the extract being due to a weak organic acid present as an impurity.

In its action on isolated guinea-pig uterus and its toxic effects in mice gorse extract behaves like the raspberry-leaf extract studied by Burn and Withell (1941), but the two extracts seem to be quite dissimilar in their actions on cat uterus *in situ*, isolated uterus of dog and rabbit, and isolated intestine. Burn and Withell reported that the dominant action of the raspberry-leaf extract was relaxation of uterine muscle, whereas our substance is chiefly oxytocic; unfortunately they made no tests on the human uterus. Nevertheless, in view of the effects of oestrus and gestation upon the action of gorse extract the possibility of an active principle common to the two plant species cannot be definitely excluded.

The mode of action of the extract remains to be elucidated. Atropine does not affect the reactivity of either guinea-pig or pregnant human uterus, and the response of human uterus to adrenaline is not influenced by the extract. The relaxation effect on parturient guinea-pig and non-pregnant human uteri invalidates comparisons with pituitary extract. However, to gain some idea of the oxytocic activity of gorse extract comparative tests were carried out on both guinea-pig and human uteri; they indicated that the activity contained in 1 ml. of S was roughly equal to 0.3 unit of pituitary extract. The increased sensitivity of uteri from guinea-pigs in oestrus and the altered reactivity of uteri from parturient guinea-pigs and from women near full term are of special interest; they suggest that the effects of administration of gorse extract may be largely determined by the balance of gonadotrophic hormones, thus widening the field of possible clinical application. The advantages of a common plant as the source of an oxytocic drug are obvious, provided a satisfactory method of extraction becomes available.

Summary

Extracts of gorse (*Ulex gallii*) have a specific pharmacological action on uterine muscle. An active principle has not yet been isolated, but relatively pure extracts have been obtained.

The dominant action is one of uterine contraction, demonstrable on the isolated uteri of several species, including pregnant women near full term. With uteri from non-pregnant women initial contraction is followed by abolition of tone and usually definite relaxation. A similar reversal of effect is shown by the uteri of parturient guinea-pigs. In intact virgin cats intravenous administration results in uterine contraction accompanied by a sustained rise of blood pressure.

Uterine reactivity to gorse extract appears to be conditioned by the balance of gonadotrophic hormones, being greatly increased by oestrogen sensitization.

It is a pleasure to record our indebtedness to Mr. L. B. Patrick, by whose courtesy all the human uteri were obtained. Our thanks are also due to Mrs. Wilson Smith for technical assistance and to B. Ibbotson, Esq., of Ashopton, for his help in the collection and preliminary treatment of the gorse. The expenses of the work were defrayed by grants from the Medical Research Council.

AN ANALYSIS OF ACUTE RESPIRATORY CONDITIONS IN AFRICAN SOLDIERS

BY

W. W. MacNAUGHT, M.C., M.B., Ch.B.
Lieut.-Col., R.A.M.C.; Officer in Charge, Medical Division

AND

R. M. MURRAY-LYON, M.D., F.R.C.P.Ed.
Major, R.A.M.C.; Medical Specialist

Before proceeding to the Tropics medical officers, also invariably are sent to a course on tropical medicine, and are taught at length the various tropical diseases which they are likely to encounter; but no stress at all is laid on the incidence of the common respiratory affections nor on the susceptibility of the African to these. It therefore comes as a surprise to them to find that almost a third of their acute medical admissions comprise conditions similar to those seen at home. The object of this paper is to emphasize the importance of these conditions and to demonstrate the response to treatment as compared with that of Europeans. It is based on the occurrence of respiratory diseases in Africans treated at a West-African general hospital over a nine-months period from June 1, 1942 when the hospital was opened. This period covers the changing climatic conditions, including the maximum and minimum temperatures and humidities.

The total number of admissions to the African Medical Division of the hospital during the period under review, excluding dermatological cases, was 1,250, and of these the high figure of 375 (30%) were respiratory infections, including the upper respiratory conditions—e.g., coryza, sinusitis, and tracheitis. Of all these respiratory infections one only was an example of tropical disease. This patient was a soldier admitted with profuse haemoptysis, and was found to be suffering from paragonimiasis, which responded rapidly to emetine therapy. The remaining non-tropical cases were divided as follows:

I.	Acute lobar pneumonia	76
II.	Bronchopneumonia	52
III.	Acute pleurisy	159
IV.	Bronchitis	7
V.	Pulmonary tuberculosis	1
VI.	Lung abscess	67
VII.	Minor upper respiratory infections	

Acute Lobar Pneumonia

The physical signs in these cases show no difference from the classical signs seen in a European, apart from a higher incidence of upper-lobe consolidation. The African patient in many instances would report sick at an M.I. room or the reception tent of the hospital, and on examination be found to have complete consolidation of one or more lobes of the lungs. Although this is occasionally met with at home it is much more common among African patients. The commonest complaint when questioned is pain in the chest, even in the absence of an audible friction rub. Little importance can be attached to an increased respiration rate, as this is common to all febrile conditions in Africans and they rarely complain of cough.

Treatment was by oral administration of sulphapyridine in full doses, and in very severe cases the intravenous route was employed for the first one or two doses. The response to this was more dramatic than in the European; for it was a common experience to find the patient on the danger list out of his bed whenever his temperature dropped to normal, although all the signs of consolidation were still present, and in no case were any ill effects of this seen. In spite of the apparent rapid recovery of these patients, radiological examination proved that resolution was no quicker than in the European, in whom the disease appears to run a slower course. It was found that the mean period of stay in hospital in these cases of lobar pneumonia was 21.8 days.

In this series of 76 cases there were only two deaths; one of these occurred within a few hours of admission, and at necropsy the case was found to have been complicated by

pneumococcal meningitis. The other patient, who was admitted in a desperately ill condition, died after four days, showing no response to sulphapyridine. Post-mortem examination revealed red hepatization of one lung and extensive fibrosis of the other, with dense, almost cartilaginous, pleural adhesions. Only two cases showed any complications. One developed a sterile effusion which absorbed satisfactorily, and was only 35 days in hospital; the other developed a lung abscess which finally healed by fibrosis after many weeks.

As the hospital was situated in a hyperendemic M.T. malarial area all patients had routine blood films examined for malaria parasites. Parasites were found in only two cases, which were treated with quinine in addition to sulphapyridine.

Bronchopneumonia

The 52 cases in this group were acutely ill on admission and showed signs of generalized bronchitis, with areas of patchy consolidation in both lungs. A productive cough was a prominent feature. They were treated by the oral administration of sulphapyridine, which was followed by a drop in temperature less dramatic than that in lobar pneumonia, but their recovery was rapid and complete. Only one case showed any complication, and that was an interlobar effusion which absorbed completely without interference.

There was no single death in this group, whose mean stay in hospital was 20.5 days.

Pleurisy

In every one of the 12 cases the symptoms were fever and pain in the chest, and a dry friction rub was found on physical examination. In no instance did an effusion develop. The treatment consisted of sedative cough medicine and heat in the form of kaolin poultices. The majority of these patients were examined radiologically and showed no evidence of any tuberculous focus.

The mean stay in hospital was 17.2 days, and none had been readmitted for a chest complaint over a follow-up period of from 2 to 6 months.

Pulmonary Tuberculosis

The 7 cases of pulmonary tuberculosis were confirmed by radiographs and sputum examination. With one exception they all had extensive lesions of the exudative type, with little evidence of resistance. The one exceptional case had an acute flare-up of a chronic fibroid phthisis, which settled down again with rest in hospital. One of the more active cases was admitted with a massive pleural effusion, which partly absorbed and recurred on three occasions. Contrary to tradition and our expectations, the incidence of pulmonary tuberculosis is low, and when seen was of the acute adult type, and no case of Ghon's focus or other evidence of the primary infection of childhood was seen.

All these cases were medically "boarded" and invalided from the Service.

Lung Abscess

One soldier was admitted in a very toxic state, having just returned from a month's leave in a bush village up-country. On examination he was found to be emaciated, with a swinging temperature and copious foul sputum. Radiographs showed two cavities with fluid levels in the right lung. He did not respond to treatment, and died ten days after admission. At necropsy a large abscess cavity was found in the right upper lobe, extending down to involve the middle lobe, and this had burst into the pleural cavity just before death. The left lung showed scattered areas of bronchopneumonia.

Bronchitis

This was the largest group in the series, and consisted of 159 cases. Five of these cases were acute exacerbations of chronic bronchitis, and the men were invalided from the Service; of these five, three had a superadded asthmatic condition. The remaining 154 patients had acute infections, one having an associated asthmatic element not severe enough for invaliding. They all responded readily to expectorants and inhalations, and required only a few days in bed. In four instances malaria parasites were found in routine blood films, and these patients responded to quinine.

The mean stay in hospital of these bronchitic patients was 11 days.

Minor Upper Respiratory Infections

This group included cases of coryza, pharyngitis, tracheitis, and sinusitis. They had been sent to hospital owing to a considerable pyrexia, which in practically all instances lasted at most 24 hours, when the patients were convalescent, apart from the very small number (five) suffering from sinusitis. In none of these cases were malaria parasites found.

Discussion

There is clear evidence that the African is much more susceptible to acute respiratory infections in the Tropics than the European. During the period under review there were only a few cases of bronchitis and minor upper respiratory infection and no cases of pneumonia or bronchopneumonia in the European wards of the hospital. Chill would appear to be a very important precipitating factor, as shown by the three peaks of high incidence of respiratory infection during the nine-months period. Two of these peaks were associated with the arrival of fresh troops after transit by sea entailing sleeping on deck, when the night cold of a moving ship affects the African severely. The third peak occurred in January, when the weather is at its coldest and the Europeans are at their fittest, with a low sick rate.

It is worthy of note that in all this series only six showed malaria parasites, whereas in the European any acute infection, by lowering the general resistance, allows latent malaria to manifest itself.

Although respiratory infections are seen to be the cause of much sickness, with removal to hospital and temporary loss of man-power, they respond readily to treatment. Serious complications are rare and the death rate low, and the permanent loss of man-power to the Army is very small.

Summary

Of 1,250 admissions to the African wards of the medical division of a general hospital in West Africa, 375 (30%) were acute respiratory infections.

Only one of these cases was of tropical origin, being an instance of paragonimiasis.

There were only two deaths among 76 cases of acute lobar pneumonia (2.6%). No deaths occurred in 52 cases of bronchopneumonia. The third death in the whole series was that of a soldier admitted with advanced lung abscess.

Complications were very rare: among the lobar pneumonia cases, one lung abscess and one sterile effusion; and one interlobar effusion in a case of bronchopneumonia.

An important aetiological factor in these respiratory infections appears to be a degree of chill not affecting Europeans.

The mean stay in hospital for the various groups was as follows: lobar pneumonia, 21.8 days; bronchopneumonia, 20.5 days; pleurisy, 17.2 days; bronchitis, 11 days.

Our thanks are due to Brig. R. A. Hepple, O.B.E., M.C., late R.A.M.C., for permission to publish this article.

NIGHT VISION IN THE ARMY

REPORT OF 10,333 TESTS

BY

A. LISTER, F.R.C.S.

Major, R.A.M.C.

AND

J. W. BISHOP, M.B., Ch.B., D.O.M.S.

Lieut., R.A.M.C.

The purpose of this article is to give additional facts to those already published by Rycroft (1942) and Craik (1943) on the conditions of the Army night-vision test and to place on record the results of a large number of tests.

Rycroft has already given an account of the Army night-vision test apparatus. In this series a certain modification of the technique described by him was employed, and is mentioned below. The brightness figures in Table I have kindly been supplied by Dr. K. J. W. Craik of the Psychological Laboratory, Cambridge, who designed the test. He has asked us to emphasize that these figures are approximate only, because the

filter material (neutral cellastoid) through which the pentagon screens are regarded is not perfectly neutral. It is slightly blue. He points out that, in comparing the results obtained by different types of adaptometer, the colour of the light can make a big difference to the visibility of the light at low illuminations for a constant brightness at high illuminations.

It is also emphasized that the test is one of scotopic visual acuity and not of minimum light threshold. Though this is so, the brightness of the screens as seen through the filter (see below) corresponds closely with the absolute light threshold of 1 to 10 micro-millilamberts (Duke-Elder, 1942).

TABLE I.—Showing Brightness Figures. (The pentagon screens are tabulated in ascending order of brightness)

Screen	Brightness of Screen	Brightness as seen through Filter
1	0.012 c.f.c.	—5.52 log. c.f.c. = 3.0 μ ml.
2	0.021 "	—5.28 " " " 5.2 "
5	0.031 "	—5.10 " " " 8.0 "
3	0.051 "	—4.90 " " " 12.5 "
4	0.095 "	—4.621 " " " 24.0 "

The subjects in this series were from first-class units demanding a high standard of physical fitness and composed largely of volunteers. The purpose of the test was to find men who could be recommended as especially suitable for responsible posts in night operations and to eliminate from operational personnel men with poor night vision. The procedure was briefly as follows:

The men were taken in groups of five or six. Each group was dark-adapted for 30 minutes in dark goggles of a density which, with the lighting conditions, resulted in the first 10 minutes being spent in dim twilight and the last 20 in darkness. Each subject was then tested separately; his goggles were removed and he regarded the pentagon through the windows of a viewing-screen. An easy side of the pentagon was presented to him first, after which the sides were presented in any order. Five seconds was the maximum allowed for any one side at a time. Marks were awarded according to the most difficult side for which two consecutive correct answers were given. Each subject was handed a ticket showing

TABLE II

Age	Total	5/5	4/5	3/5	2/5	1/5	0/5	Average Marks for Each Age
18	43	20	14	8	1	0	0	4.23

his marks. The group left the dark-room together, and handed their mark tickets to the recording clerk. A group could be tested in this way within five minutes. One hundred and fifty is a convenient number of men to test in a day, but over two hundred can be dealt with without undue fatigue.

The viewing-screen mentioned above is glazed with goggle-glasses—"triplex," the middle element being a neutral cellastoid

filter. Its advantage over goggles is that the space around the eyes is not closed. Fogging is thus prevented or greatly diminished, and can easily be attended to by means of a good quality "anti-dim" substance. It also ensures that the same density of filter is used for all subjects. The results of the series of tests are shown in the accompanying Tables and Graphs.

TABLE III.—Distribution of Marks in Total

5/5	4/5	3/5	2/5	1/5	0/5
32.4%	35.4%	19.6%	8.7%	2.4%	1.5%

TABLE IV.—Distribution of Marks in Age Groups

	5/5	4/5	3/5	2/5	1/5	0/5
18-22	39.0%	35.5%	16.6%	6.3%	1.7%	0.9%
23-27	30.4%	35.3%	20.5%	9.6%	2.2%	1.4%
28-32	27.1%	35.5%	21.3%	10.7%	3.1%	2.0%
33-37	23.1%	34.9%	23.8%	10.3%	4.6%	3.1%
38-55	24.4%	34.4%	25.0%	7.5%	6.3%	2.5%

A large majority of the subjects had visual acuity of 6/ or better in both eyes, without glasses, so that no comparison can be made of scotopic with photopic visual acuity.

The fundi of all the men who received low marks were examined, but in those that were examined no pathological changes were found. Where there are no fundus changes cause of poor night vision is often obscure, and it is of difficult in such cases to assess the truth of the subject's answer. While most of the men with 1/5 and 0/5 stated that they did not see well in the dark, a few were emphatic that they had no difficulty, and it is probable that 0/5 just include the minimum end of the range of normal scotopic vision.

Fig. 1.—Table IV in diagrammatic form.

Fig. 2.—Results in graphic form. Ordinates=Average marks out of five. Abscissae=Age groups.

If the brightness is raised two stages, so that that of screen No. 4, as seen through the filter material, is between 60 and 70 μ ml., 1/5 comes within the range of the pathologically night-blind, since this screen has been found to be visible under these conditions to one or two cases of retinitis pigmentosa.

The results correspond fairly closely with those obtained by Steadman (1943) using a different adaptometer. Rycroft

obtained a considerably higher proportion of men with 0/5—7% in even his best group. This discrepancy is probably mainly due to difference in technique, and emphasizes the advantage of the viewing-screen over goggles. In spite of constant attention the latter become fogged and are a source of error.

The chief interest of this series of results is the illustration it gives of the downward trend of scotopic vision which occurs with advancing years. According to these results the drop begins before the age of 18. Since, however, the drop from the average at 18 to that at about 44 is only in the region of 3 μ ml., this point is of theoretical rather than of practical importance.

Summary

The brightness figures of the Army night-vision test are given, with a qualifying remark on the colour of the light in adaptometers. Though the test is one of form sense it appears that the minimum light necessary for the discrimination of a simple form is in the region of the absolute light threshold.

The results are recorded of 10,333 tests, the subjects of which were high-category men between the ages of 18 and 55. They illustrate the downward trend of scotopic vision which occurs with advancing years.

We wish to thank Brig. Sir Stewart Duke-Elder, Consultant Ophthalmic Surgeon to the Army, for permission to publish this article; also Dr. Craik, to whom the first part of the article is due.

FILARIASIS IN THE MIDDLE EAST

BY

J. FINE, M.D., Major, R.A.M.C.

AND

Dr. LIVNY, Civilian Medical Practitioner

It is not unusual to meet with cases of clinical filariasis among African native troops in the Middle East, and one of us (J. F.) has seen them in all three hospitals to which he was temporarily attached.

In view of the high incidence of microfilariaemia among natives in certain regions of Africa reported in the literature, it was considered of interest to carry out a routine examination of the blood of all negro patients in the wards of a general hospital, irrespective of the condition for which they were admitted. At the same time information was obtained of the country of origin in each case and the period that had elapsed since they left their homes: in practice this period corresponded to the time of enlistment. The findings are shown in Table I.

An inspection of the table revealed that: (1) 12 cases (29%) out of 42 showed the presence of microfilariae; (2) 30 out of the 42 patients came from Uganda, and all the positives were in this group—i.e., Uganda soldiers showed 40% infestation with filaria; (3) of the 12 cases of filariaemia only two had clinical filariasis; (4) the patients with filariaemia had left Uganda from 10 months to 2 years and 8 months previously.

An attempt was made to determine the species of filaria present by doing relative counts morning and evening. The results appear in Table II, the number of filaria recorded being the total found in an entire uniform wet film.

It is clearly impossible to infer the species in more than three cases in this series: of these three one was *L. loa*, the other two *W. bancrofti*. Unfortunately there was no opportunity of continuing the investigation to determine the diagnosis by more frequent counts or by staining methods.

One point of interest that emerges is the large number of instances (10) in which only one larva was present in an entire wet film. In those cases an average of 15 minutes elapsed before the larva was found, and it is not unlikely that a less leisurely examination would have yielded more negative results: five such negative results were in fact reported by a laboratory assistant whose speedy disposal of 20 films (in about 50 minutes) roused suspicions as to the reliability of his findings. In view of the number of films with only one larva in the entire specimen it seems probable that some of the negative results

might have been positive if a greater volume of blood was examined, or if a concentration method was used at which a quantity of blood was haemolysed and a centrifuged deposit examined. The use of thick films, dehaemoglobinized and stained, should also increase the number of positives in a filarial survey.

The transmission of filariasis is by a wide range of insects. Manson-Bahr instances 24 species of mosquito capable of transmitting *W. bancrofti*, and these include 8 culicines, 11 anophelines, 3 aedes, and 2 mansonioids; among those are *Culex fatigans*, transmitted by mangrove-flies only (*Chrysops*), while the intermediate hosts of *A. persans* are limited to the midge genus *Culicoides*. It is clear, therefore, that malarious areas such as occur in the Middle East are likely to favour the dissemination of *W. bancrofti* infection, and even though the incidence of clinical filariasis is not high among infested individuals, it does not seem desirable to expose non-filarial

TABLE II

districts to the consequences of introducing heavily infested bodies of troops such as the Uganda natives.

The scope of the present investigation is admittedly too limited to justify any sweeping recommendations such as the cessation of recruiting in endemic filarial areas of Africa. Nevertheless it does seem desirable to introduce a routine blood-film examination for natives in such areas and to assign infected cases for local duty only. Whatever precautions might be taken with infected troops (segregation, mosquito netting), the great length of time, extending into years, during which filariae are present in the blood stream renders the probability of eventual dissemination one of definite proportions.

Summary

Forty-two sick African native soldiers in a Palestine general hospital were examined for microfilariæ and 12 positives were obtained.

Thirty out of the total came from Uganda, and all the infected cases were in this group.

Only two of the positives were cases of clinical filariasis, but it did not seem very likely (though this has by no means been established) that the conditions from which the other ten cases suffered had any relation to the filariaemia.

Most of the infected men had left their homes over a year ago, and in some cases over 2 years before; filariaemia must therefore have persisted for long periods, and must be regarded as capable of persisting still further.

Pending fuller investigations it is suggested that natives in known infested areas should not be recruited for service abroad unless the blood is found to be filaria-free.

THE DETERMINATION OF HAEMATOCRIT VALUES IN WOUND SHOCK

A ROUTINE PROCEDURE

BY

MAX REISS, M.D., D.Sc.

(Endocrinological Department of Burden Neurological Institute,
Bristol)

In the course of certain experimental work it became necessary to devise means of determining the haematocrit value of many blood specimens simultaneously and with the utmost speed. Our requirements were met very simply by (1) the use of thin-walled capillary tubes; (2) millimetre paper; (3) a specially constructed fixed-angle microcentrifuge slotted to hold 25 capillary blood specimens. This apparatus allowed the haematocrit value of the blood from several cases at one time to be determined with accuracy and with such unusual expedition that we feel justified in describing our technique in detail.

Method

The capillary tubing is drawn out and cut into approximate lengths of 60 mm.; from each specimen heparinized blood (small droplet of blood on finger dusted with heparin before pricking) is filled into 8 to 10 such tubes by capillary attraction.

These are then quickly sealed at the uncontaminated end in a spirit flame—taking care not to heat the blood—fitted into numbered grooves in the special centrifuge, and spun. Since the rate of spin depends on the motor power available for connexion to the instrument, the higher the rate of spin the shorter need be its duration. The capillary tubes may be removed as soon as the solid constituents of the blood are

spun out, and the reading is made by checking the fluid-solid level against millimetre paper. The resultant average of all samples of each blood specimen is expressed, as usual, as the percentage of corpuscles in a total blood volume.

The body of the centrifuge (see Fig.) is a truncated cone with a top diameter of 3 in. and a bottom diameter of 6 in., the external surface being at an angle of 45 degrees with the base. The sets of capillary tubes slide into grooves cut from top to bottom of the external surface parallel to its inclination and are retained by three narrow bands running round the outside of the cone at intervals of about 20 mm. between base and top. Underneath, and turned as part of the cone, is a horizontal pulley-drive. The entire head is mounted on a vertical 1/2-in. steel rotating shaft. The shaft is fixed on a universal clamp so that the apparatus can be secured firmly on a table, metal framework, rod, or other platform sufficiently robust. The centrifuge head can be constructed of light metal or some lighter material, so that no great driving power will be needed. A small electric motor is adequate, or the power provided by the fan belt of a motor-car or similar engine. In practice it has been found quite satisfactory to drive the centrifuge by pressing the lower rim against the upper outer side of the tyre of a jacked-up rear wheel of a motor-car. It might be more convenient to interpose a small driving wheel and flexible shaft of speedometer type. In cases where the r.p.m. are low a step-up pulley could be easily interposed between motor and centrifuge to raise the gear ratio so as to yield about 3,000 to 4,000 revolutions a minute. Where such fittings are lacking or the available centrifuge-mounting is not firm enough to allow such a high rate of spin, satisfactory results can be obtained with as few as 1,000 revolutions a minute; but in this event the tubes must be spun for a longer time. The lowest optimal time for every individual connexion can be found once for all by the initial inspection at test intervals of a set of control tubes. When the solid-fluid level ceases to alter, the end-point has been reached. The spinning time so determined will be approximately correct for all subsequent readings under the same conditions. No harm is done by considerable prolongation of the spinning time, where it may be convenient so to do. The usual precautions taken with other types of centrifuge in regard to their slowing gradually to rest without disturbing the content of the tubes should also be observed here. Where a drive is provided by a car engine the r.p.m. should be reduced by gradual deceleration.

This simple centrifuge has proved so useful in the laboratory that its use may be suggested as an aid to clinical differential diagnosis in surgical emergencies.

Comment

Modern investigations in the mechanism of production of shock in the injured have shown that in primary shock the collapse is due to vasomotor failure; the composition of the circulating blood is unaltered and transfusion of blood or plasma is not indicated; it may even overload an already impaired circulatory system. The haematocrit readings will be within the normal range of values. In secondary shock the haematocrit readings will be abnormally high owing to loss of fluid elements of the blood; the percentage of solids in any given blood volume will be in considerable excess of normal. If secondary shock is still developing and not yet extreme the patient is still conscious, but the underlying progressive blood change is already revealed by a moderately raised haematocrit reading.

Haemoconcentration has been found to be the earliest sign of oncoming shock in wounded soldiers (Moon, 1942).

Transfusion of plasma, though an appropriate treatment for all degrees of secondary shock, can confer only temporary benefit if the excessive capillary permeability persists (that has allowed the migration of fluid constituents of blood, and the transfused plasma also escapes. It has been found, as in the case of burn shock reported among others by Rhoads (1941), that adrenal cortex hormones (cortin) are capable of preventing the persistent fluid loss by reducing capillary permeability, thereby saving much plasma. Dehydration shock experiments

in the rat (Reiss, MacLeod, and Golla, 1943) have shown that corticotrophic hormone, by mobilizing an endogenous supply of adrenal cortical hormones, can similarly influence the capillary permeability and effectively prevent the loss of blood fluid.

The haematocrit alone can give a differential diagnosis of the state and fate of the fluid components of the blood.

Medical Memoranda

An Unusual Amoebic Liver Abscess

It is common knowledge that the metastatic liver infection produced by the *Entamoeba histolytica* proceeds in many cases from hepatitis to suppuration. The resultant abscess must always be thought of as the "cold" variety and be treated with as much circumspection as are those due to the *Mycobacterium tuberculosis*. This lesion progresses, and seeks to establish an outlet whose track may lead into any structure which is in immediate anatomical relation to the liver. Adhesions will form in practically every case, and so prevent general contamination of a serous cavity.

Many years of observation have shown that the amoebic liver abscess is usually solitary and large, and is situated in the right lobe. Again, in the case of the female, liver abscess is relatively uncommon. Rogers observed nearly 400 cases of liver abscess in Calcutta, 97% being in males, and quotes Ludlow's series of 240 cases in Korea, of which 90% were in males; while Manson-Bahr states that European women in the Tropics rarely develop the condition. The undermentioned case presented several uncommon features, in addition to the fact that the abscess occurred in the left lobe and in a female.

CASE NOTES

On Dec. 28, 1939, I was asked to see a parous Hindu, aged about 30, who complained of weakness, fever, general abdominal discomfort, and anorexia. The symptoms came on gradually, without rigors, and were associated with some loss of weight of only twelve days' duration. The fever was at first remittent, and quinine had been given for thirteen days, but without result.

Examination showed a fairly well nourished woman, and the following signs were recorded: coated tongue; no abnormal glands; chest, heart, and C.N.S. normal. The abdomen was held in a tense manner, but a mass filled its upper half, and it was dull to percussion though not very tender. Rectal examination and urine analysis were normal. Blood serum for agglutination contained *B. typhosus* 1:1280, but the Vi agglutination test gave a negative reading.

Stools showed no abnormality on gross examination. On the 15th day of fever the temperature became intermittent. Re-examination revealed that the liver edge was at the level of the navel, and that another mass in the upper abdomen came from behind the costal margin and extended two inches below the navel. There was a notch at the junction of this mass with the liver. It felt like an enlarged spleen, but subsequent signs showed it to be an enormous left lobe of the liver. No shifting dullness was found, nor was the mass very tender. On the 15th day the blood showed 15,000 white cells per c.mm., with 84% polymorphs. Stools were repeatedly negative for ova, cysts, and amebae. A course of 104 gr. of emetine hydrochloride injections was given over a period of 15 days and the temperature became normal, but only for the first three days. On the 19th day signs appeared at the right base—viz., dullness, absent breath sounds, and inspiratory rales.

Shoulder pain and vomiting never occurred. The patient now began to lose weight at an alarming rate and the temperature was swinging from normal to 103° F. She could with difficulty be encouraged to take fluids and glucose. There was no sweating, and the urine showed only a trace of albumin. On the 20th day the white cells were 16,600 per c.mm., and on the 21st day rose to 19,600.

Under twilight sleep and local infiltration with novocain the right lobe of the liver was searched diligently, but with no result. Then the needle was directed into the greatly enlarged left lobe and 58 oz. of light yellowish-green fluid resembling thin pea-soup was removed by means of a Potain aspirator. This immediately relieved the patient, and the temperature kept at the normal level for 7 days. The emetine course was then stopped and the same signs and symptoms recurred. On the 32nd day of the disease aspiration was repeated after the white cell count had risen to 24,400. On the 37th day a further 16 oz. of thicker and darker material was aspirated. The patient continued to lose weight and strength, and for the first time the skin and sclera became icteric and there was choluria, associated with an irregular curve on the temperature chart.

As repeated aspirations failed to achieve a cure, and as the abscess in the left lobe could be seen standing out and fluctuation could be obtained there, open drainage was done.

Operation.—Under local anaesthesia the left rectus was split, and on a nick being made in the oedematous peritoneum odourless pus, thick and with coagula and sloughs, shot forth. Using Bailey's method of a tube within a tube and eusol irrigation, together with extreme care in the changing of dressings, secondary infection was avoided. The patient was discharged healed on the 30th day after operation. She was given stovarsol 4 gr. b.d. in a 10-day course and tab. ferrous sulph. 3 gr. t.d.s. for a month after operation, and is now fit for a normal day's activity.

The Third Case of Fatal Air Embolism reported after Vaginal Insufflation

Recently details of a death due to air embolism following a picotrol insufflation of the vagina was reported by Dr. Latham Brown. The fatality occurred in a normal primigravida one week before she was due. The clinical picture and post-mortem findings of our case are almost identical to his. They will be stated to emphasize that air insufflation of the vagina in a pregnant woman near term is a very dangerous procedure.

CASE HISTORY

On June 4, 1943, a 1-para aged 21 was admitted to Ashridge Hospital. Her expected date of confinement was June 8. She was completely normal in every respect except for a malodorous vaginal discharge due to the *Trichomonas vaginalis*. On June 6, two days before she was due, it was decided to treat the discharge with a picotrol insufflation. Approximately ten pumps of the insufflator were used—i.e., about 600 c.cm. of air. The patient did not complain of any undue discomfort. When the insufflator was withdrawn she immediately went into what appeared to be a fit. Her eyes rolled up, she became very cyanosed, her pulse became imperceptible, and despite all attempts to resuscitate her she died within about three minutes.

At necropsy the woman appeared well nourished but cyanosed. Air was found in the heart, making the blood in the right side appear frothy. The neck veins had the appearance of overfilled spirit-levels, air showing through the walls. Air was likewise found in the sinuses of the brain. It was also abundantly present in the pampiniform plexus. The uterus contained a normal foetus at term. The placenta was situated high up on the anterior surface. The membranes were not ruptured. Air could be seen through the veins on the outside of the uterus. The cervix was large, inflamed, eroded, and patulous. Although we looked very carefully, we could find no evidence of bleeding, separation of the membranes or placenta from the uterine wall. However, a considerable amount of air was found on the maternal surface of the placenta. In the last case reported the membranes and a portion of the placenta were found stripped from the uterine wall. In that instance it was obvious that the air entered the circulation from the vagina by passing through the cervix, stripping up the membranes, and thus getting into the maternal sinuses of the placenta. The same route must be presumed in our case.

DISCUSSION

We are in entire agreement with the views stated arising out of Dr. Latham Brown's case, and think they should be repeated—namely, that it would be a pity if such an efficient form of treatment as picotrol insufflation should fall into disrepute on account of three fatalities in many thousands of normal cases, when precautions might guarantee its harmlessness. We also agree that an efficient cervical barrier must be demonstrated before insufflation is used, or some other form of treatment should be adopted.

It would seem that as the mode of entry of the air into the circulation is through the placental site, insufflation is only dangerous in a pregnant woman. Let us consider the question, Is insufflation dangerous throughout the whole of pregnancy or only in the later months? These two cases show that it is definitely dangerous in late pregnancy. In the other case, reported in Canada in 1936, death occurred in a multigravida only 4 months pregnant. Since the placenta is fully developed in form by about three months it would seem that there are present in miniature all the factors which are capable of allowing air to enter the circulation from then onwards. In all probability the danger of air embolism increases as the placenta enlarges and the os becomes more patulous. In other words, the later in pregnancy the more dangerous is the treatment. The treatment is also probably more dangerous in multigravida women, as their cervical barrier is less efficient.

Conclusion.—In early pregnancy it would be prudent to hesitate before insufflating a patient; and in late pregnancy dogmatism is justified—it must not be done.

(In fairness to the makers of picotrol, in their literature they state that insufflation should not be done in the last four months of pregnancy.)

Ashridge Hospital.

Reviews

THE LYMPHATIC SYSTEM

The Lymphatic System: Its Part in Regulating Composition and Volume of Tissue Fluid. By Cecil K. Drinker. Lane Medical Lectures. Stanford University Publications: University Series. University Science, Volume IV, No. 2. (Pp. 101; Illustrated. 14c.) California: Stanford University Press; London: Oxford University Press. 1942.

This series of five lectures makes entertaining reading, and maintains the high standards of the Lane Lectures. It is entertaining because the treatment of the subject is original and the author's asides both sagacious and witty, and it maintains the high standards demanded by tradition by reason of the originality of the approach. Space will not permit of long quotations, but the following might well be put up in large letters in many a laboratory. "It is a misfortune that those who apply the idea that living creatures are but complicated expressions of the natural laws which they slowly learn from studies of inanimate objects, measure the reactions of living things with a rod whose every mark is stamped with the authority that can be established for non-living material."

The keynote of the lectures is that the lymphatic system can best be understood by consideration of its essential connexion with the circulatory system, with which it is integrated into a means for maintaining a constant internal environment for the tissues. The historical development of this point of view is attractively treated, as is also the author's search for a biological explanation of the evolution of lymphatics, a subject that still remains somewhat obscure.

The interdependence of blood, tissue fluid, and lymph is elegantly illustrated by the author's own recent work on the lymph flow from the heart and lungs. This work is not only in itself a triumph of technical skill but an excellent illustration of the general principles involved, and, moreover, is likely to be of importance in the pathology of the organs concerned. The last chapter deals with the relation of the lymphatic system to practical problems of medicine and surgery, and shows how a knowledge of the relations between blood, tissue fluid, and lymph throws light on some long-established practices.

INSTRUCTION FOR NURSES

A General Textbook of Nursing: A Comprehensive Guide. By Evelyn C. Pearce, 8th Edition. (Pp. 915; Illustrated. 15s.) London: Faber and Faber. 1943.

Teaching in Schools of Nursing. By Alice M. Jackson, M.A., and Katharine F. Armstrong, D.N., S.R.N. With an Introduction by Cyril L. Burt, M.A., D.Sc. (Pp. 244. 7s. 6d.) London: Faber and Faber. 1943.

Miss Evelyn Pearce has revised her well-known volume *A General Textbook of Nursing* for an eighth edition, a surprising record when it is recalled that it first appeared as recently as 1937. Changes have been made in accordance with advances in treatment, so that there is now a note about penicillin and an interesting new "routine" for the dressing of surgical cases. What seems to be missing is not so much the latest form of treatment as a more up-to-date outlook on the whole future of nursing. The term "social medicine" does not appear in the index, and the part that nurses must play in the social and preventive medicine of the future is not stressed. The word "almoner" does not appear in the index, though mentioned in the text in a brief manner in connection to the discharge of patients.

A reprint of *Teaching in Schools of Nursing* by Miss Alice M. Jackson and Miss Katharine Armstrong has now been issued and appears to be identical with the first edition published in 1934. Here again the new orientation in the world of medicine is lacking, although in an appendix on the "block" system of training the curriculum includes two lectures by the hospital almoner on social services.

CONTROL OF INSECT PESTS

Biological Control of Insects. By Hugh Nicol. (Pp. 174. 9d.) Pelican Books. Middlesex: Penguin Books. 1943.

"Biological control," says Dr. Nicol, "has been practised by every person who has kept cats on account of the mice. . . . With this deceptively simple example he encourages the layman to study the complexities of modern achievements in biological control of pests. Nature is a battleground in which innumerable forms of life compete to live and reproduce. By agricultural

practice man has swayed the ecological balance, but in the course of centuries it has become readjusted in Europe and Asia. The matter is otherwise, however, in recently developed areas of the world, farmed on the largest scale. The constant movements of commerce have brought to these lands insect pests without parasites or competitors to hamper them. The results have been destruction spreading like a forest fire. Chemical and mechanical control measures have achieved little success in these cases, and the apparently obvious procedure of collecting and destroying the pest was entirely useless. Only by the use of scientific observation and experiment were the missing biological checks discovered and brought, perhaps, thousands of miles to the new country. The remarkable success of these measures in many countries was well deserved by the perseverance of the entomologists concerned. Dr. Nicol describes many such campaigns, each presenting different features of interest. Unusual scientific terms are explained, but there is no attempt to "write down" to the reader, who is perhaps, more likely to be a scientist or medical man than a average citizen. There are some good illustrations.

Notes on Books

An abridgment of Mr. J. G. CROWTHER's book *Soviet Science*, published in 1936, has now appeared as a ninepenny "Pelican." The original material was collected during seven visits to the U.S.S.R. between 1929 and 1935, when the foundations of contemporary Soviet scientific and technical strength were laid under the First Five-Years Plan. A large public will welcome this hand and inexpensive edition.

Preparations and Appliances

EMERGENCY SPLINT FOR FRACTURED FEMUR

Major P. L. W. WILLIAMS, D.S.O., F.R.C.S.E., Battalion Medical Officer, 4th Cornwall (Wadebridge) Battalion, Home Guard, writes:

An emergency splint for fractured femur (and adjustable for leg bones) has been made up entirely with personal equipment, which can be applied by two untrained men in the absence of skilled assistance. The photograph shows it applied to a member of the Home Guard.

Directions

Place the casualty in extended position; limbs together. One man grasps heel and foot of injured limb, makes steady extension, and maintains it until bandaging is completed. The other places rifle along outer side, butt well up to armpit, first removing bolt, ensuring that neither rifle nor magazine contains any cartridge, and extracting pull-through; then ties boot-

laces together and, with large handkerchief or field dressing, puts a figure-of-eight bandage round rifle, ankle, and boot, tying off on sole of boot; then encircles upper part of chest with one of their belts, and hips with another, passing each one when length permits, round the rifle first. Two field dressings are next applied, pads on wound as far apart as possible, short end of bandage to outer side, long end brought round under thigh, round the rifle, then over and round both thighs and tied off to the short end, knot on rifle. Finally, a pair of anklets buckled together is placed round both legs just below knees and then buckled up, and the pull-through cord passed round them and tied to give the anklets a firm grip on the legs.

I wish to make acknowledgments to Dr. H. C. Harley, who showed in a letter to the *Lancet* that the men's personal equipment could be effectively used for fixation of the rifle, and to the Editor of *Journal of the R.A.M.C.* for permission to reproduce this

PSYCHIATRY AT THE CROSS-ROADS

It is not too much to say that the future of psychological medicine—or psychiatry, as it is now almost popularly called—is of fundamental importance for medicine as a whole; not only because of the frequency of psychological ills and causes of illness and of psychiatric problems in the community generally, and in special domains of human life and experience, but because of the pervasiveness of psychological factors throughout the art of medicine. The last war opened the eyes of many to psychological problems in medical practice previously hardly suspected. The present war has made that experience vider and deeper. It is curious how at one and the same time the most conservative and the most progressive teaching in medicine is reinforced by psychiatric experience. In clinical psychiatry diagnosis still rests firmly on a thorough clinical history and not primarily on examination by medical or laboratory methods—a principle that still applies equally to general medicine, where, however, it is more easily obscured and forgotten. The social aspects of medicine, to which everyone now pays at least lip service, are nowhere more evident than in psychiatry, the most socially oriented of all the medical disciplines. The new message of “positive health” is already recognized in the efforts of psychiatrists in the fighting Services and their colleagues, the “academic” psychologists, to select the fittest for the multifarious but specialized tasks of war.

In these times of change and progress psychiatrists find themselves in a position where as pioneers they must expect to find themselves—opposed by conservative and even sometimes by reactionary forces of the what-was-good-enough-for-the-Services-in-1900-is-good-enough-today type—but they are in distinguished company. In one direction, however, the war has given point to questionings which had long existed and for which remedies had been sought in vain. We refer to the training of psychiatrists. To put the matter plainly, the qualifications of some psychiatrists for the tasks assigned to them are unsatisfactory, and they could have been far better. It is not solely or even mainly the fault of the psychiatrists. When the University of London raised the standard of its D.P.M., what happened? The number of candidates quickly dwindled, because most candidates were content to take the D.P.M. of other examining bodies whose standards were less exacting. When it was suggested to some of these that they should stiffen their requirements they found objections, and any change made was hardly perceptible.

Apart from the unsatisfactory examination position, many psychiatrists suffered and still suffer from the fact that mental hospitals, where most of them live and work, provide a limited though valuable and indispensable type of experience, but one which fits them in only a one-sided fashion for the great bulk of extramural psychiatric work. Attendance once or twice a week at an out-patient department is useful but does not restore the educational balance. On the other hand there are many psychiatrists who have never held an appointment in a mental hospital—it is as if someone would seek to be a specialist in surgery without having held a resident surgical post. This deficiency in the experience of the most serious and profound

mental disorders is not by any means completely compensated by residence and work in a psychiatric clinic or hospital for “early” or “recoverable” cases exclusively, essential as such experience undoubtedly is for the thoroughly grounded man. Psychiatrists have themselves been to blame in allowing such accidental and unfortunate differences of experience to appear fundamental, so that a school of “organicists” (*sic*), who seem almost innocent of psychological knowledge or insight, became opposed to schools whose principal or only study was psychotherapy; while psychiatrists trained for the most part within mental hospitals have regarded with professional suspicion those trained for the most part outside—and vice versa. The cause of these schisms, which to visitors from abroad seem sometimes as puerile as they are avoidable, lies largely in the nature of our psychiatric institutions—using the word in the sense of established things, and including examinations as well as hospital organization—and in particular in the fact that almost alone of Western countries Britain has failed to develop in-patient accommodation in special units inside general teaching hospitals. The advantages of such units, commonly known abroad as psychiatric clinics, are many, but in general they help to confer not only on future psychiatrists but on medical students a comprehensive outlook on mental disorder, and a psychological as well as a physical orientation towards the problems of everyday practice.

The poverty of training in psychological medicine in many of our schools has been in some ways almost scandalous. In few has the student had a proper introduction to the subject. There have been in places a few lectures, not always valuable in spite of their comparative rarity, some demonstrations of the more advanced type of mental disorder, and little else. A few schools have done much better than this, but their resources have been scanty, with few or no teaching beds for in-patients and crowded and inadequately staffed out-patient departments. The teachers of the subject, it is true, got little encouragement from the programmes of the curriculum. The last Curriculum Conference, of which much had been hoped, turned out to be very timid and tepid in its recommendations. All this has put psychiatry at a disadvantage in the medical schools. Those students who chose a psychiatric career found that the main avenue to it led them away from medicine as a whole, into relative isolation from their colleagues in other branches. They found also that the generally low standard for the D.P.M. made it possible for the most slenderly equipped person to set up as a “specialist” with an undeniable academic qualification.

To remedy this state of affairs, by beginning at the most remediable end—the education of a new generation of psychiatrists—a committee presided over by Sir Walter Langdon-Brown has drawn up a scheme for an approved D.P.M.¹ In its report published recently the committee recognizes several fundamental principles. It considers that the practice of psychiatry is not one in which students of one year of graduate age should blossom as fully equipped specialists as they can do under the present regulations. Four years’ postgraduate training is recommended as the minimum before the D.P.M. can be taken. It also provides that the aspirant will not rush straight from medical school into specialist training, but must obtain experience of general medicine first of all for at least a year in hospital or in general practice. Thereby the report recognizes in a practical way that psychiatry and general medicine are “very much mixed up together,” and will be more so in the future. The subject-matter of psychiatry is not nowadays only the relatively few who are alienated from

¹ Report of the Langdon-Brown Committee on Postgraduate Training in Psychological Medicine. Published June, 1943.

ordinary life. The motto of the psychiatrist of to-day—and especially in the period of training—might well be *Humani nihil a me alienum puto*.

The Langdon-Brown Committee recognizes that no one can practise psychiatry with full effectiveness, sympathy, and understanding unless he has spent a year or two in close contact with mental disorders in their most profound forms. The creation of special units—psychiatric clinics—in general hospitals, necessary as this is, will not remove the need for residence in a mental hospital as part of the specialist's or consultant's training. The ideal training will include both. In the meantime the Committee makes the best of the existing facilities by recommending a year's attendance at psychiatric out-patients in a teaching hospital.

Disagreement may be found with the details of such a scheme, but the general principles implied in it—of length and diversity of training, and of contact with general medicine—are likely to command wide acceptance. The report of the Committee should be of great help in all future deliberations on the same subject, which is one of urgency, not only for psychiatry but for the application of sound and comprehensive medical principles to the development of the post-war world. It is not a symptom of a mania for planning: it is a remodelling which works with the organizations that exist, pending the construction of a better *milieu* for the training of practitioners in psychological medicine. The report is fair, constructive, broad-minded, and brief.

MOSQUITO BREEDING IN STATIC WATER TANKS

The extent to which mosquitoes in this country give rise to serious annoyance is not so widely appreciated as it ought to be. It is true that no question of transmission of serious disease, as in the Tropics, ordinarily arises; but the nuisance effect is widespread, and in the summer months countless persons suffer minor tortures from bites of mosquitoes which might be largely avoided if sufficient attention were given to control of these insects. The introduction of static water tanks in our towns has recently brought this question rather prominently into the foreground, forming a sanitary problem which for some time has been engaging the attention of local authorities—namely, how far are these to be regarded as possible sources of mosquitoes and what action in this connexion ought to be taken.

An account lately given by its Director, Mr. John F. Marshall, on the activities of the British Mosquito Control Institute, Hayling Island, in the City of Portsmouth,¹ gives some very pertinent information on these points. To oil all tanks, without more information as to how far they are actually being utilized by mosquitoes as breeding places, might be very wasteful as well as objectionable where tanks are waterproof-lined with bitumen, on which oil would have a prejudicial effect. Again the English species most likely to breed in such tanks, *Culex pipiens*, rarely if ever bites human beings, though on the other hand static water contaminated with sewage or other nitrogenous matter would be liable to breed the fierce and poisonous mosquito *Theobaldia annulata*; and static water stored in dark underground situations—for example, in "basement tanks"—may be expected to breed the almost equally fierce *Culex molestus*. In the present case the Medical Officer of Health of Portsmouth, Dr. A. B. Williamson, with the co-operation of the Hayling Institute, arranged to carry out a systematic inspection of all tanks in the

city area. The tanks were of seven types—namely, oblong and circular steel tanks, brick-and-concrete and concrete tanks, clay-lined tanks, basement tanks, and excavated sumps. The great majority were filled with fresh water, but sea water was used in a certain proportion of cases. As the result of some seven months' close inspection only two species of mosquito—*Culex pipiens* and *Anopheles maculipennis*—were found breeding, and the latter only in tanks containing algae and during the late autumn. A positive find was made before May 7 or after Oct. 6. Mr. Marshall points out, this result was not due to absence of other species in the area, since the mosquito *Theobaldia annulata* habitually and heavily infested garden tanks in which "manure water" was kept for plant-watering purposes, while *Anopheles claviger* and other species of mosquito were present, including certain "coastal species" of *Aedes*, often a serious pest in seaside localities and very troublesome in the environs of Portsmouth until their control was taken in hand. Why these mosquitoes did not avail themselves of the breeding facilities offered by the tanks was not very clear, but one must suppose that their own special and particular habits did not "fit in" with the conditions which the tanks provided. One reason was probably the size of the tanks, since the smaller the tank the more likely was it to contain larvae. No difficulty was found in treating tanks where larvae were detected by the clearing of algal growth and dilling where this was appropriate. In only one instance did reinfection take place.

The practical importance of this careful piece of research needs no emphasis. The only cautionary comment it is perhaps advisable to make is that conditions in different localities no doubt vary a good deal, and the results found in one locality might not be exactly reproducible in another, the main deduction to be drawn being the necessity for a proper supervision wherever such tanks exist. One would desire to compliment the public health authorities at Portsmouth on their action in the face of unknown potentialities in arranging for such a survey as Mr. Marshall on this example of the work of the Hayling Institute, which for many years has been carrying out research of great scientific interest and public utility on British mosquitoes and their control. Besides describing the Portsmouth investigation, the pamphlet published by the Institute gives much useful information on the general question of breeding in static water and would well repay perusal by those who may be interested in this subject.

VOLUNTARY HOSPITALS LOOK FORWARD

Special interest attaches to the speech of the chairman (S. Bernard Docker) at the annual meeting of the British Hospitals Association because it indicates the general line upon which the association's discussions with the Ministry of Health have proceeded. He said that certain principles were fundamental to the fulfilment of the Government's declared promise to retain the voluntary hospitals—namely, individual hospitals must keep their freedom and flexibility in the administration of their own affairs and the appointment of their staffs, and the patient must be free to choose not only his doctor but also his hospital. The B.H.A. had suggested a central hospitals board, the members of which would be appointed by the Minister on the nomination of the parties concerned—the voluntary hospitals, local authorities, and doctors. This board would advise him on the general plan and policy, on local schemes, and on the allocation of certain money, including that provided centrally from social security funds. It should be free to make suggestions and recommendations to the Minister and

¹ The Control of Tank-breeding Mosquitoes in the City of Portsmouth. British Mosquito Control Institute, Hayling Island, Hants.

publish reports. Sir Bernard Docker here defined the extent of the responsibility of local authorities by saying that they should see that the facilities available in their areas were adequate; he did not say that they should provide these facilities. Local advisory hospital boards, he continued, should be set up, constituted in the same way as the central board except that a university in the area should be represented on it. These local boards would advise the health authorities on the provision of hospital services in the area and the part to be played by each hospital. They should be autonomous, independent of local politics, with the right of appeal in case of dispute to the central hospitals board. On the question of finance, he said that if voluntary hospitals were to be preserved then they must still be able to receive voluntary contributions and the public to make donations—this in addition to a contribution from the Government out of social security funds and payment from local authorities for services rendered and from patients for maintenance. Contributory schemes would continue: it was at present being considered how they could best be maintained and utilized in a comprehensive health service. The Minister of Health, who was the guest of honour, after acknowledging the help the B.H.A. had given him, said the discussions had dissipated the idea (which was quite unfounded) that some kind of onslaught was being planned against the voluntary system. That was a complete misconception. The Government's policy was and always had been to make the fullest use of voluntary resources in any post-war hospital service.

THE SHORTAGE OF MIDWIVES

Though there was an increase in the number of women enrolled as midwives during the past year, and a further steady rise—of nearly 1,000—in the number of pupils received in the training schools, the shortage of women practising the profession still causes anxiety, according to the report of the Central Midwives Board for England and Wales. It is hoped that the recommendations of the Rushcliffe Committee and the Advisory Council for the Recruitment and Distribution of Nurses and Midwives will secure that the necessary proportion of pupil-midwives continue in practice after qualification. A special survey of Part II training schools has been made on behalf of the Board, especially with a view to looking into the conditions under which pupil-midwives live and work, in the endeavour to assess the extent to which these factors may influence the pupils in their choice or rejection of the profession after qualifying. Some useful information has been elicited and is now being considered. The roll of midwives on March 31 last contained 67,112 names, being 1,480 more than at the end of March, 1942. The number who notified their intention to practise during 1942 was 15,868. Of this number only five were untrained "bona-fide midwives"—that is, enrolled by virtue of having been in bona-fide practice before the passing of the Act of 1902. Of the midwives practising in 1942, 56% had been enrolled during the thirteen years since 1930. Out of 16,000 midwives enrolled in the six years 1935-40 only about 27% notified their intention to practise in 1942. It is estimated that the proportion of enrolled midwives who are or have been married must be nearly 48%, and very few married midwives work in institutions. The need for adequate housing for the practising midwife, with special reference to recommendations of the Rushcliffe Committee, was brought to the fore at a conference held in London on Aug. 30 by the College of Midwives. Several speakers,

including medical men with first-hand knowledge, pointed out the handicaps under which the midwife lives and does her work and the discouragement to recruiting that arises therefrom.

CHEMOTHERAPY IN SWITZERLAND

The *Schweizerische Medizinische Wochenschrift* has recently published a magnificent special number (No. 19/20, 1943) on chemotherapy, which is dedicated to the International Committee of the Red Cross. Its 140 large pages are devoted to articles by Swiss authorities on almost every aspect of sulphonamide therapy, including both the treatment of various types of disease and such more general matters as chemistry, pharmacology, nomenclature, mode of action, the assessment of therapeutic success, and the conduct of treatment in children and the aged. It is noteworthy that a greater range of different sulphonamide compounds appears to be on the market in Switzerland: a table of formulae and correct chemical descriptions with corresponding trade names includes a total of 22 different substances. In the purely clinical articles sulphathiazole appears to be a strong favourite for most purposes. It is encouraging to find that, according to G. Bickel, the recovery rate in endocarditis lenta has risen to 6%: he emphasizes the need for a prolonged course of heavy dosage, and gives a total of from 800 to 1,200 g. of sulphathiazole. Before embarking on so serious an undertaking as this it might be well to determine the sulphonamide sensitivity of the streptococcus concerned; the absence of instructions for performing such tests is one of the few omissions from among possible subjects in such a symposium. M. Grob reports a reduction in the mortality of perforative appendicitis in children from 16 to 1.6% after adopting the method of scattering a mixture of sulphathiazole and boric acid powder in the peritoneal cavity after appendicectomy. There is a very valuable paper by N. G. Markoff on blood changes produced in the course of treatment, with particular reference to marrow changes and effects on haemopoiesis, but including descriptions of sulph- and met-haemoglobinaemia and other effects on the blood. On the academic side a noticeable feature is some degree of scepticism about what may be called the *p*-aminobenzoic acid theory. While fully acknowledging the validity of Fildes and Woods's fundamental discovery, more than one author questions whether this is the whole explanation of the sulphonamide effect on bacteria. As a detailed reflection of practice and belief in a most enlightened and at present regrettably inaccessible country this number is of exceptional interest.

DIET OF WORMS

The manner in which tapeworms obtain their nutrients has long been a matter of speculation rather than of observation. It is commonly believed that they depend for their nourishment on the digested or semi-digested intestinal contents in which they are bathed, and which they absorb by diffusion through the body surface. This has long been assumed, but never verified. Very little work has been done on the effect of variations in the diet of the host on the persistence, growth, and reproduction of tapeworms, most of our knowledge on their nutrition and physiology having been obtained from worms kept in various nutrient media *in vitro* or from chemical analyses. Several facts suggest that adult tapeworms may absorb nutrients directly from the mucous membranes of the gut of the host rather than from the food products in its lumen. Thus some

adult tapeworms can live outside the lumen of the intestine and have their head and neck deeply embedded in the intestinal mucosa; others live in the liver, gall-bladder, and bile ducts. Immature tapeworms can also develop in such tissues as the liver and muscles, under serous membranes, and even in the brain.¹ Still another reason² for believing that tapeworms may not depend entirely on the nutrients in the intestinal lumen is the strong host specificity of most species, which suggests that they depend, in part at any rate, on the host's tissues for food.

Recently experiments by Chandler³ with *Hymenolepis diminuta* in albino rats prove that this tapeworm is wholly independent of the protein in its host's diet, for complete elimination of protein from the latter had no evident effect on the establishment, growth, or reproduction of the tapeworm, though it made the rats lose a lot of weight. Chandler has also produced evidence that the tapeworm is independent of vitamins A, D, E, and B, in the diet. It seems plain, therefore, that the worms absorb these vitamins and proteins—or at all events nitrogenous substances—directly from the mucous membrane of the host's intestine. On the other hand it appeared that the tapeworms got the bulk of their carbohydrate and vitamin B₁₂ complex from the contents of the intestinal lumen. Perhaps some part of the vitamin B complex is necessary for the utilization of carbohydrate by the worms.

The popular idea that tapeworms are injurious to their hosts primarily because they rob the host of unabsorbed food may need revision. The general systemic effects commonly produced by tapeworms—e.g., nervous symptoms, gastro-intestinal disorders, loss of weight, and weakness—may be due not to toxins but to the absorption by the worms of vitamins, proteins, and other essential factors from the gut wall. Symptoms of frank vitamin deficiency have not so far been reported in patients infested with tapeworms, though Chandler believes that tapeworm toxicity may be in part an induced vitamin-B deficiency; but other worms can cause avitaminosis and anaemia.² In this connexion the precipitation of a macrocytic anaemia resembling pernicious anaemia by infestation with the tapeworm *Diphyllobothrium latum* (*Dibothriocephalus latus*) is of some interest. It is generally agreed that in pernicious anaemia an extrinsic factor, contained in meat and yeast, is converted into anti-pernicious-anaemia factor by the action of an intrinsic factor secreted by the stomach. It is possible that one of these factors is absorbed by *Diphyllobothrium* in large enough quantity to cause anaemia in the human host.

HEALTH AND TONSILLECTOMY

A feature of medical practice in recent years has been the popularity of tonsillectomy, especially among patients of well-to-do families; over half of the children in boarding schools have had their tonsils removed. Paton,⁴ in his analysis of the data relating to 424 girls at boarding schools, of whom 42.9% had a history of tonsillectomy, suggested that this operation was carried out too readily, and that the tonsillectomized group had no advantage over the group who were not operated on. Since this inquiry a mass of material has been collected by the School Epidemics Committee of the Medical Research Council.⁴ The data were based on the records of an average number per term of over 10,000 boys and 3,500 girls during 1930-4. Of the children studied 56% of the boys and 50% of the girls had

had their tonsils removed. The sickness experience of the tonsillectomized group was no better than that of the children in whom there had been no operation; in fact there was some slight indication that the incidence of rheumatism, otitis media, and mastoid disease was higher among the former. A comparison of the sickness incidence before and after the operation was made for a selected group of 364 boys who had their tonsils removed on the advice of the school medical officer. Before operation this group had an attack rate for nasopharyngeal infection which was 8.7% greater than the expected rate obtained from age distribution and rates of all boarding schools combined. After tonsillectomy the attack rate was 0.5% less than the expected rate. The committee concluded that in properly selected cases an operation was of real value but in general it was performed for no particular reason and with no particular result.

A further contribution to the subject has been made by Paton,⁴ which extends his previous study to the decade 1930-9. The data are based on the records of 909 girls, of whom 57% had had a tonsil-adenoid operation, compared with 43% in the earlier study. The physique of the girls who had undergone operation was similar to that of the girls who had not been operated on, and girls of exceptionally low weight and height and above the average were as common in the one group as in the other. Common colds were more frequent among the tonsillectomized than among the rest, the rates being 114% and 97% respectively. Influenza was also slightly more prevalent among the former group—43%, compared with 39%. Only a few cases of tonsillitis occurred during the ten years, the tonsillectomized group having a slightly better record with a rate of 1%, compared with 5% for the other group. All other cases of sore throat were as frequent in the one group as in the other, the rates being 40% for those who had been operated on and 41% for the remainder. Susceptibility to the common infectious diseases of childhood was about the same in both groups, 26% of the tonsillectomized children and 24% of the others contracting these diseases. There was a considerable difference between the two groups for bronchitis, the rate among the tonsillectomized being 27%, while for the others it was only 16%.

An interesting comparison was made of the experience of the girls who had tonsils only removed and those who had an operation for adenoids only. The rate for bronchitis and for otorrhoea among the group who had only their tonsils removed was 23% and 0%, while the rates for the other group were 4% and 8% respectively. The number of girls concerned, however—tonsils only 57, adenoids only 24—is too small for definite conclusions. The author suggests that the removal of tonsils is the factor in the combined operation which is responsible for the reduction in tonsillitis and for the increase in respiratory infections, while the removal of adenoids alone reduces the incidence of respiratory infections but increases the liability to attacks of otorrhoea. In the combined operation the removal of adenoids failed to counteract the increase in respiratory diseases which resulted from the removal of the tonsils. This study supplies additional evidence to support the view that a large proportion of the tonsil and adenoid operations in children are unnecessary, entail some risk, and give little or no return, while a reduction in their number would not have any unsatisfactory result and might, perhaps, be beneficial.

The doyen of our profession, Sir Thomas Barlow, Bt., M.D., F.R.S., celebrated his 98th birthday on Sept. 4.

LISTER INSTITUTE OF PREVENTIVE MEDICINE FIFTIETH ANNIVERSARY REPORT

The report of the Governing Body of the Lister Institute for 1943 is noteworthy as marking the fiftieth anniversary, not of the incorporation of the Institute, which took place in 1891, but of the beginning of its active operations. Sir Henry Dale, P.R.S., has been elected chairman of the Governing Body, and Dr. Alan N. Drury has succeeded Sir John Ledingham as director. The Governing Body has placed on record its appreciation of Sir John Ledingham's devoted work for the Institute over a period of 38 years.

Much of the research described in the annual report has already appeared in the journals, some of it in these columns, notably Felix's papers on the typhus group of fevers and on the typing of typhoid bacilli by means of Vi bacteriophage, the paper by Korenchevsky, Hall, and Clapham on the effects of vitamins on experimental hyperthyroidism, and that by Petrie and Steabben on the identification of the chief pathogenic *Clostridia* of gas gangrene.

Dysentery Prophylaxis

In a series of experiments designed to avoid the toxic reactions of a bacterial Shiga vaccine, H. L. Schutze has found that mice inoculated with diethyleneglycol extract of *Bact. shigae* develop a considerable immunity. With a mortality of 90 to 95% among the untreated, a survival rate of 60 to 80% may be expected among the inoculated. The optimum spacing of vaccine doses has been found in the case of the Shiga bacillus to be of some importance in establishing maximal immunity to infection. A definite superiority has been shown in the protection afforded when inoculations are separated by six weeks as compared with a shorter interval. The stability of this diethyleneglycol extract in the presence of preservative has been tested, and formalin and merthiolate have been found not to damage its potency. Inoculations of a small group of human beings have been carried out. The reaction was minimal in some, in others more pronounced, but of short duration and not excessive.

From experiments on the antigens derived from *Bact. shigae* and the protective action of their antisera, Steabben draws the inference that in the treatment of dysentery in man antitoxic serum containing an antismatic or "anti-endotoxic" component may be of prime therapeutic importance as an adjunct to chemotherapy. Such a serum will not only neutralize the toxin but may also arrest bacterial invasion if given at the earliest possible moment. Further, as the serum possesses both antitoxic and antibacterial components it should also be of value in the prophylaxis of dysentery in man in an epidemic.

Substances inducing Tissue Permeability

Research has been carried out by McClean and others on the enzyme hyaluronidase. Experiments on its role in fertilization have shown that the transparent viscous fluid or gel in which the cumulus cells of the rat ovum are embedded is dissolved by hyaluronidase from any source, with disintegration of the cell mass. A close correlation has been found between the viscosity-reducing activity of the enzyme and the rate of denaturation of the egg, no matter whether the enzyme comes from testis, spermatozoa, bacteria, or snake venom. This observation may perhaps explain why a reduction in the sperm count rapidly leads to sterility, as there would be a corresponding reduction in the concentration of the hyaluronidase in the neighbourhood of the egg.

It has been found that when the infecting organisms of the gas-gangrene group produce hyaluronidase this enzyme can be detected in the oedema fluid as soon as enough can be collected for examination, and in the muscle as soon as the earliest sign of infection appears. A large proportion of *Cl. welchii* strains associated with clinical gas gangrene produce hyaluronidase; all the strains of *Cl. septicum* which have been examined produce it, but only a small proportion of those of *Cl. oedematiens*.

Digestibility of Wheat Grain

Nutritional studies along several lines have occupied many workers at the Institute. Sir Charles Martin and others have tried to ascertain the degree to which the contents of the aleurone cells in the bran of wholemeal (100% extraction of the wheat grain) are made available during digestion. Of the extra 25% of the grain contained in wholemeal about 15% is bran, which consists of the outer integuments of the grain and the closely adherent aleurone layer, the latter containing as much as one-fifth of the total grain protein. Rats fed on diets in which finely ground bran was the only source of protein were killed, and the contents of the various portions of the alimentary tract collected separately, examined microscopically, and analysed for nitrogen content. The protein and fat of the aleurone layer were found to be utilized to a large

extent by the rat, the cells losing their contents chiefly in the small intestine and caecum and occasionally also in the stomach. The nitrogen of the bran had an apparent coefficient of digestibility of about 60%, compared with about 83% for that of wholemeal (100% extraction) and 89% for that of white flour (75% extraction). In human trials the degree of disintegration of the bran observed on microscopical examination of the faeces, though variable, was similar to that which occurred in the rat.

A study of the faeces of rats fed on diets in which the protein was derived respectively from wholemeal, white flour, wheat bran, potato, and milk showed that the bacterial fraction of the faeces was lowest and contained the least percentage (36) of the total faecal nitrogen when the diet was composed of bran. With a wholemeal flour diet the bacterial fraction contained 53% of the total faecal nitrogen. When the diet contained white flour or milk the dry weight of the faeces passed was much lower and the bacterial fraction contained about two-thirds of their nitrogen, and the same was true more or less of a potato diet.

Nutritive Value of the Potato

Compared with wheat, most varieties of potato have a much lower nitrogen content, and since less than half of this nitrogen is in the form of protein certain researches have been continued by Chick and others to determine the nature of the other nitrogenous compounds and their nutritive value. Preliminary tests with young growing rats have shown that the protein (tuberin) separated from juice squeezed from the raw potato possesses a biological value slightly superior to that of the proteins of whole wheat, notwithstanding the fact that the latter are more digestible and better absorbed. It has been found possible to rear young rats from weaning on a diet containing whole cooked potato, fresh or dried, as sole source of nitrogen. The variety used was the "King Edward," grown on the fenlands and containing a rather high nitrogen content. The nutritive value of the protein separated from the potato and of the total nitrogen as contained in the tuber is much greater than that of the whole nitrogenous concentrate prepared from raw potato juice, containing only the more easily extracted nitrogenous substances.

Other Nutritional Studies

A nutritional survey covering 374 women employed in Oxford factories and 288 housewives in the same locality revealed a relatively high incidence of goitre and of dorsal spinal curvature, the latter being diagnosed in about 7% of 553 women examined. Many cases of dorsal spinal curvature have also been found among Oxfordshire school children. A connexion is suggested with low iodine and high fluorine content of water and soil, and the matter is being further studied.

Investigations on vitamin C in plant metabolism have shown that the vitamin content of unripe green tomatoes is considerably lower than that found in red tomatoes ripened in store after the season is over. Tomatoes ripened in store attain a vitamin C content similar to that of fruits ripened on the plant.

The relative effects of butter and margarine in preventing fat-deficiency disease in rats when added to a completely fat-free diet have been examined, and butter has been found to be rather less effective than margarine in preventing this condition. This is held to dispose of a suggestion that the increased substitution of margarine for butter in wartime diet is a responsible factor in producing dry and scurvy skins.

The Lister Institute's collection of type cultures, housed at Elstree, received some 150 new strains during the year under review.

NAGUIB MAHFOUZ PASHA ADMISSION TO HONORARY F.R.C.S.

Surg. Rear-Adml. G. Gordon-Taylor, as Senior Vice-President of the Royal College of Surgeons of England, recently admitted to the Honorary Fellowship Prof. Yudin and Prof. Burdenko during the visit of the British-American Surgical Mission to Moscow. On his way back from this arduous journey Adml. Gordon-Taylor also admitted to the Honorary Fellowship Dr. Naguib Mahfouz Pasha, professor of gynaecology in the Fuad University, Cairo. The ceremony took place in the presence of a large number of members of the Senate and of the Medical Faculty of the University, and many British and American officers. By a happy chance three members of the Council of the College of Surgeons were also present. Another coincidence, and a pleasant one for Egypt, was that the ceremony took place on the day it was announced that Mussolini was deposed from power. We print below the text of Adml. Gordon-Taylor's address of welcome to the new F.R.C.S.

"Naguib Mahfouz Pasha, the Council of the Royal College of Surgeons of England by unanimous vote elected you an Honorary Fellow of the College over three months ago. This is the highest honour which the College can bestow; the Honorary Fellowship is limited to 50 names, and is conferred almost unreservedly upon those who have distinguished themselves in surgery, whatever be their country or clime. This chance though fleeting visit of mine to your country suggested to the President that I might be charged with the pleasing task of presenting you with the insignia of the Fellowship amidst your colleagues in Cairo, the scene of your meritorious surgical work. The story of Great Britain cannot compete in years with your historic land, whose civilization goes far back for millennia and aeons of years into the dark backward and abyss of time; far less can our College claim to vie with you in the tale of the centuries. Nevertheless our ancestral saga stretches back dimly for over four hundred years, and as the College of Surgeons our existence dates from the earliest dawn of the nineteenth century. This is not the first time that this honour has come to Egypt. His Majesty the late King Fuad graciously accepted the honour; a second recipient is Sir Ali Ibrahim Pasha, Director of the University Hospitals and Dean of the Faculty of Medicine, the doyen of Egyptian surgeons and respected of all men.

"In awarding you this honour, Naguib Mahfouz Pasha, the Council of the Royal College of Surgeons of England recognizes your distinguished work in your own special branch of surgery; and the pre-eminent position which you hold in the world of gynaecology; it also bears in mind the wondrous museum illustrating the problems of the maieutic art which was created by your own labours, and it further recognizes your administrative ability, your efforts on behalf of medical education in Egypt, and your staunch allegiance to the Allied cause. It is perhaps not inappropriate, although exceptional, that this honorary Fellowship is being conferred upon you far beyond the precincts of that building in Lincoln's Inn Fields, battered and burned by Hun air attack. It is sometimes in adversity and misfortune that we find our truest friends, and you surgeons of Egypt made haste to assure us with your promises of aid to restore, recreate, and reconstitute a temple of anatomy and pathology worthy of the name of John Hunter and of his tradition. It is, then, perhaps not unfitting that to-day's ceremony should take place in your own historic land, where obstetrics already existed as a surgical specialty in the fourth millennium before Christ."

Reports of Societies

ASCORBIC ACID IN IDIOPATHIC METHAEMO-GLOBINAEMIA

At a meeting of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland Dr. J. DEENY, Prof. H. BARCROFT, and Prof. D. C. HARRISON presented a communication on familial idiopathic methaemoglobinaemia and its treatment by ascorbic acid, describing the condition in two brothers.

Only two other instances of this disease had been found in the literature (Bensley *et al.*, 1938; Lian *et al.*, 1939). In the present instance cyanosis was persistent and dated from birth in one case and from before puberty in the other. The face and hands of both brothers were slate-coloured. General health was good, and one brother played hockey although his blood contained nearly 50% of the total blood pigment in the form of methaemoglobin. There was no history of drugs. Deeny (1940) had reported that ascorbic acid and sodium carbonate had a favourable effect on two cases of polycythaemia, and he had investigated the possibility that this treatment might also be of benefit in the cases of cyanosis due to methaemoglobinaemia. The first of the two brothers to be given this treatment showed a dramatic improvement and cyanosis disappeared in about 10 days. In the second brother the cyanosis similarly disappeared, and frequent determinations of methaemoglobin in his blood showed that it fell from 43 to 6% of the total blood pigments in about a month. At the same time there was a fall in the total pigments, in the red cell count, and in the reticulocyte count. Both brothers had now been on the treatment for a year and the improvement was maintained. At the time the authors were not aware that Lian *et al.* (1939) had already observed the favourable effect of ascorbic acid on a case of this disease; they also confirmed the latter's finding that ascorbic acid could

convert the methaemoglobin in these patients' blood into haemoglobin *in vitro*.

Dr. DEENY read clinical notes of two cases and described treatment in detail; the patients, he said, were blue in color and were normal after the treatment. Prof. HARRISON described the pigment changes which occurred during the treatment. The pigment was intracorpuseular and there were no other abnormal pigments. Prof. BARCROFT, discussing the rarity of cases, searched through the literature had shown altogether 12 since 1930 and none before. Of these only six were definite familial—Dr. Deeny's two, two in Paris, and two in Monte-A feature was the persistence in the colour: in 9 of the cases it had been there since birth, and in the other 3 since before puberty. All had good general health; all showed tendency to polycythaemia. Treatment consisted of an intravenous injection daily of 100 mg. of ascorbic acid. All patients improved.

RECENT EXPERIENCE OF WAR NEUROSIS

A meeting of Allied psychiatrists was held at a base hospital over-seas on June 5, when Lieut.-Col. S. A. MACKEIT presided, and the subject for discussion was war neurosis.

Lieut.-Col. R. R. GRINKER (U.S.) said war neuroses did not constitute a clinical entity with characteristic and invariable symptoms. Statistics of frequency were unreliable as cases were diagnosed by different psychiatrists, and the syndrome varied from day to day and place to place. There were nine syndromes: (1) free floating anxiety, severe and moderate (2) somatic regression; (3) psychotic states; (4) conversic symptoms; (5) depressions; (6) psychosomatic visceral disturbances; (7) anxiety complicating concussion states; (8) exhaustion states; and (9) fatigue states, particularly in flying personnel.

Severe anxiety states were characterized by psychological and physical manifestations of terror. The patients were fearful apprehensive, and showed bizarre and peculiar behaviour patterns. There were marked tremor, intolerance of noise and a startle reflex. Only a few islands of normal behaviour persisted. Some persons were mute and dependent like a child others showed varying degrees of stupor, mutism, and amnesia with little evidence of anxiety. There was thus a splitting of the personality in these cases resembling schizophrenia, and as such they were often erroneously diagnosed. In patients with moderate anxiety states there were insomnia, tremor, restlessness, and signs of sympathetic over-activity; they had severe battle dreams and were intolerant of noise. They recollected well the source of their anxiety and rapidly seemed able to control it. The clinical condition, however, was no index of the severity of the precipitating trauma or the quantity of anxiety beneath the surface. This could only be brought out by pentothal or during air raids, which were a good test of the patients' stability.

Patients with somatic regressions looked as if they had organic disease of the brain from which they had "recovered" completely. The regressions took the form of severe foetal pictures and attitudes, extrapyramidal symptoms of rigidity, coarse tremors, masked facies, excessive sweating, propulsive gait, etc. In some there were severe speech defects. In many there was no conscious anxiety: the emotion was only liberated as the symptoms disappeared. In group 3 severe anxiety states with paranoid projections occurred. The paranoid element indicated hostility within the patient; with proper care these people could be restored. Group 4 was the only one in which the term "hysterical" was justified. Physical symptoms of a defensive nature like deafness, visual difficulties, and regressive phenomena like astasia-abasia or stuttering were included in this group, which contained only a few true cases of conversion hysteria. These were usually in the form of weakness, monoplegia, hemiplegia, sensory defects, or numbness. They seemed directly related to a minor injury at the traumatic site. The patients were blandly without emotion, but when the symptom was relieved there was severe anxiety.

Depressions were seen, especially in the obsessed person. Many were acutely precipitated by war situations and often

associated with gastro-intestinal symptoms. The dependent passive type reacted by depression, which continued after the anxiety was reduced. Psychosomatic visceral disturbances were most often observed with gastric conditions. Very few cardiac syndromes had been seen, in contrast with the last war. All egresses of anorexia, abdominal pain, nausea, and vomiting were observed in persons with little subjective anxiety, or with apprehension only about their symptoms. Enuresis for the first time and diarrhoea were other psychosomatic symptoms.

Concussion states were frequently complicated by anxiety states, which had to be treated first; the residual headaches, lizziness on change of posture, intellectual difficulties, and isual disturbances had to be treated by long periods of rest. To force these patients to get up and back to duty was not rational therapy for the concomitant neurosis. Exhaustion states were seen especially in the forward area; very few cases had been handled at the base. In patients who apparently came into this category there was usually much unconscious anxiety. Fatigue states were found only in flying personnel, and constituted an incipient neurosis caused by mobilization of anxiety and tension without opportunities for proper release. The actual neuroses in airmen were little different from those in other Services. There were few severe anxiety states. They were mostly mild anxieties, depression, gastric dysfunction, and conversion states. In all these cases the influence of secondary gain was important. The individual had become dependent and learnt to live with limited resources. Unless early treatment was started the influence of secondary gain increased, and the individual would continue to be dependent and lean on the State.

Place of Narcosis

Capt. SPEIGEL (U.S.) thought that sodium pentothal, which produced a semi-narcotic state in which the patient could face the traumatic battle situation and relive it with proper emotional response, was indicated in all cases of severe war neurosis with stupor, mutism, somatic regressive and regressive psychosis-like manifestations, and amnesia. Response was dramatic; in most instances there was rapid recovery from major symptoms, but in more severe cases a series of four or more treatments might be required. The residual anxiety and associated symptoms had to be dealt with by psychotherapy. Pentothal was also indicated in moderate anxiety and conversion states to determine the intensity of, and to release, unconscious anxiety. It was also useful in concussion states to distinguish symptoms due to anxiety from those of organic origin. Subsequent treatment consisted of a series of half-hour interviews with the patient. The psychotherapist had to establish a positive transference identification, assuming the role of the sympathetic but firm father figure, reassure the patient that he would not have to return immediately to combatant duties, deal directly with the anxiety by taking over the patient's temporarily lost ego functions for him, and deal with the super-ego reaction, the passive dependent trends, the conversion symptoms, and the unconscious hostility and its transfer to the super-ego in the form of depression. The last was the most stubborn psychotherapeutic problem. Hostility arose from frustration of dependent needs, from feelings of injury and abandonment in traumatic situations, from loss of object relationship through death of friends and separation from the group, and was expressed through the super-ego and directed at the ego, which became correspondingly weakened. If transference could be made sufficiently stable some of this hostility could be absorbed by the psychotherapist, but this was difficult in an active theatre of war. The aim of treatment was to return the patient to duty as early as possible. Few would be returned to full combat duty from a base hospital.

The Precipitating Factor

Major C. KENTON said that anxiety was the precipitating factor and common symptom in breakdowns, and was the basis on which the different forms of war neurosis were imposed. It was an apparent paradox that a chronically anxious man could go through so many situations producing anxiety before breaking down. Referring to the frequency and degree of psychological regression in his cases, he said it appeared as if the ego defences to anxiety were overwhelmed in greater or less degree, producing clinical pictures of stupor, confusional states, uncontrolled primitive behaviour, psychotic pictures often of a bizarre character, childishness, apparent idiocy, and, in some exceptional cases, simian behaviour. The precipitating traumatic factor, although often specific in a psychological sense, was only the final one in a long process kept under control until then. He could not agree that the suddenness of the trauma "shocked" the patient into neurosis. Discussing the response to abreactive therapy, he said that results with pentothal had been remarkable, but it should be administered only by those trained in its use; inexperienced use had made subsequent treatment

difficult, producing "pentothal-resistant" patients. Prolonged treatment after the initial improvement by abreactive and short-term psychotherapy was difficult, such factors as secondary gain, imperfect transference, and resolution of guilt feelings playing a part. Hypersensitivity to noise and fear of air attacks were frequent sequelae, facts well shown by the "testing situation" of occasional air raids. Continuous narcosis was of value in patients who showed evidence of exhaustion. These cases on the whole were rare at the base, but responded well to abreactive therapy following a period of narcosis. A characteristic of the psychoses was their episodic nature, remission and relapse occurring rapidly, often without apparent external cause. Convulsive therapy gave good results in the depressive and catatonic states. He concluded by saying that 81.5% of the patients with neuroses had been returned to some form of duty in that theatre of war—a very satisfactory result.

Experiences in the Forward Area

Capt. F. R. HANSON (U.S.) said that all cases of blast injury were diagnosed as exhaustion for administrative reasons and to avoid the diagnosis of "shell shock." Phenobarbitone 4 to 6 gr., nembuta 4½ to 6 gr., or sodium amytal 7½ gr. was given immediately by the mouth. The men were then sent to the evacuation hospital (equivalent to a C.C.S.) in a drowsy state and divided into those for immediate evacuation—severe anxiety reactions, psychotic states, and recurrent cases—and those to be kept for treatment. The latter lasted 4 to 5 days. Phenobarbitone gr. 2 twice a day was given for 3 days, after which all sedatives were stopped except for a small nightly dose. There was no impression of illness or hospitalization and men were made to get up, stand in line for their food, and help with ward routine. At the end of 5 days the patients were divided into those fit to return to combat duty and those to be evacuated. The criteria were: past history; type, severity, and cause of the reaction of the patient and whether he responded to treatment; desire to return to duty; social response and reaction to noise. No one was allowed to panic, and physical restraint was used where necessary. As the cases were all of the same type group therapy was possible. 60% of men returned to full combat duty within five days. In a follow-up of 44 cases after three weeks or further fighting 89% had remained on duty, including 1 killed and 6 wounded.

Discussion

In the discussion several speakers said that the aims of psychotherapy were: (1) to return men to full duty; (2) to return men to selective duties: over 80% at the base could be returned to such duties; (3) to treat the man's illness; and (4) to reduce the drain on the State for pensions, etc. In a great number of cases there had been difficulty in meeting the individual problems of a patient owing to the very limited number of psychiatrists. Brigade J. R. REES stated that the recovery rate curve and the number of patients psychiatrists had to deal with were directly correlated.

Correspondence

The Medical Superintendent

SIR,—I have noticed with deep regret a tendency to criticize medical superintendents from time to time in your correspondence columns. Only those closely associated with Poor Law infirmaries for the past twenty years can have any idea of the truly splendid work of these men. There was a time when the infirmary was like some tale told by Dickens illustrated by Hogarth, and the conversion of infirmaries into proper hospitals has been one of the greatest medical achievements of our time.

Surgically and administratively results obtained are remarkable because of the uphill nature of their efforts and because medical superintendents have not only had to carry out difficult reforms in the work and buildings but they have had to persuade the rate-paying public that all this was necessary. It has been no light task, and without the help of Nevill Chamberlain, our greatest Minister of Health, it could never have been achieved. Chamberlain saw the need for freeing the rate-supported hospital from the curse of the Poor Law and never ceased to support all efforts to that end.

Virtue is its own reward, and medical superintendents can well afford to ignore criticism, safe in the knowledge that they have conferred on the sick poor an inestimable benefit. At a time of great crises and anxiety it was largely to the rate-supported hospital that the country turned for help, and there could have been no Emergency Medical and Hospital Service had it not been for the devoted and fine work of medical

superintendents and their committees in creating such hospitals. Let us, then, give honour to whom honour is due, and freely acknowledge the great debt that medicine and the whole country owe to our medical superintendents.—I am, etc.,

New Barnet.

JOHN ELAM.

Vitamins and Fitness

SIR.—I have read with great interest in the *Journal* of Aug. 28 (p. 265) the paper on vitamins and physiological function by G. Neil Jenkins and John Yudkin, as, with collaborators, I have been carrying out somewhat similar investigations, a report on which is ready for publication and the results of which I cannot anticipate. Drs. Jenkins and Yudkin in my opinion are quite justified in saying that the non-induction of physiological change by the giving of vitamins to their subjects may have been due to such subjects not being deficient in these nutriment before administration began. I would like to suggest that they carry out another investigation in which they compare vitamin-deficient children (found by testing) with children who are not so deficient. Another point: in the Manchester experiment of Harper, Mackay, Raper, and Camm (*Journal*, 1943, 1, 243) the subjects were adolescents; Drs. Jenkins and Yudkin's subjects were pre-adolescents; this I am sure would make a difference. I have found differences myself (pre-war) in 14-year-olds in Gloskop, and in S. Africa E. Jokl and E. H. Cluver, while finding no differences in physical efficiency between well-off and badly off (nutritionally) children before puberty, found that after puberty there were striking differences.—I am, etc.,

Gloskop.

E. H. M. MILLIGAN, M.D., D.P.H.

Public Attitude to Venereal Disease

SIR.—I think everyone will agree that it is of vital importance that all persons suffering from venereal disease should be under treatment and kept under treatment until cured. The Ministry of Health has done everything possible to ensure that this shall be so and is spending much money on propaganda. The efforts of the Ministry are being undermined by certain misguided persons, who are doing possibly as much harm as the Ministry's propaganda does good.

It has come to my knowledge that certain employers of labour, or their managers, have threatened with dismissal, and in some cases have dismissed, persons in their employ who, they have found out, are attending a venereal diseases clinic unless they can produce a certificate stating that they are not suffering from V.D. This action presumably is taken under the delusion that they are safeguarding their other employees. I have reason to think in some cases that it is prompted by a self-righteous attitude against persons whose morals are no worse than the majority of the public.

Persons with venereal disease who are under treatment are not a source of danger to others. Those who are highly contagious are suspended from work by the medical officers of the clinics until they are no longer a danger. It is the untreated cases that are a danger, and this high-handed action by employers prevents infected persons seeking advice, and tends to prevent those under treatment continuing until cured. Moreover, these unfortunate people become ostracized by their fellow-workers, and their lives made a burden. I know of one case where a girl was thrown out of her lodgings from this cause. It is high time something was done to put a stop to this persecution. That there are many mental defects still large is shown by the notices dealing with V.D. put up by authorities in public lavatories being torn down and replaced.—I am, etc.,

London, N.W.3.

HAMISH NICOL, F.R.C.S.E.D.

Infective Hepatitis?

SIR.—Dr. John Waring in your issue of Aug. 21 (p. 228) describes a case of benign lymphocytic meningitis showing transient icterus, and immediately classifies it along with cases of gastro-enteritis, ileo-colitis, and infective hepatitis with and without jaundice—assuming on rather slender evidence that all these conditions have been due to the same infecting agent. On this assumption he would like to discard the now accepted term of "infective hepatitis," substituting for it the vague and nebulous expression "influenzal hepatitis."

That cases presenting identical symptomatology, with and without jaundice, are frequently seen together in time and place is well recognized, and in the present state of our ignorance it seems most reasonable to classify these as infective hepatitis. It is not easy to see how the introduction of such an expression as "influenzal" can do anything but darken the gloom which already surrounds these fascinating syndromes.

Had Dr. Waring given us fuller pathological findings in his case it would perhaps have been easier to accept it as an example of infective hepatitis showing meningeal changes, and might then have proved to be a valuable piece of evidence relating to the aetiology of this condition. A brief examination of the available literature leads me to believe that infective hepatitis and meningitis are but rarely seen; while, on the other hand, it is well known that leptospiral infections very frequently give just this picture. If Dr. Waring had recorded the white cell count, often of value in differential diagnosis, the blood urea level, and the presence or absence of albuminuria and cylindruria, it might have been possible to make a provisional diagnosis of Weil's disease. Even at this time—nine months after the illness—an agglutination reaction would probably clinch matters.

There is considerable evidence to-day that many of the long-recognized cases in which jaundice has unexpectedly presented—the icterus often seen in acute infections such as pneumonia, and that so often met in the therapeutic use of the arsenicals—may one day be shown to be due to a latent virus infection activated by the trauma of infection or drug. This should not, I feel, justify hurried and unconfirmed diagnostic assumptions, such as seem to have been made in this paper.—I am, etc.,

Winchester.

KENNETH M. ROBERTSON.

Precision Method of Cephalometry and Pelvimetry

SIR.—Dr. Paul Cave's article on pelvimetry and cephalometry (Aug. 14, p. 196) describes a method of x-ray mensuration which is not by any means new, but which is not generally used because it possesses many disadvantages and may, in some cases, be grossly misleading. The method is an application of the tube-shift principle, which is used in stereoscopy and foreign-body location, the only difference introduced being movement of the tube in a plane away from the film instead of in a plane parallel with the film, as is usually done.

Taking the depth-location first, all tube-shift methods depend on the production of two shadows of the object being investigated by two separate exposures taken with movement of the tube between them, the distance and direction of the movement being known. The movement of the shadow is measured on the film, and as the tube-shift distance and the tube-film distance are known, it is simply a matter of triangulation to determine the unknown depth of the object, whether it be a piece of shrapnel or the pelvic brim. Normally the tube is moved in a plane parallel with the film through a distance of 5 or 10 centimetres, producing an image-shift of the order of 1 or 2 centimetres usually, and this can be measured to half a millimetre, giving an over-all accuracy of about 2 or 3% in the depth calculation. It is usual to make each exposure about half the normal exposure appropriate to the part of the body concerned, and the whole procedure may be easily carried out on any plant, a portable unit being commonly used.

The method of Dr. Cave employs a vertical tube-shift sufficient to double the tube-film distance, making the distant exposure with this greater distance between 5 and 6 feet, which is mechanically impossible with most plants; in addition, the part-exposure made from this greater distance would have to be four times that made at the shorter distance to give equal intensity, producing greater tube wear, which we are urged by the Ministry of Health in a recent circular to avoid.

The variation in size of the two shadows he thus produces will be considerable for a large object but minute for a small one, so that the diameter of the pelvic brim would show several centimetres increase, while a foreign body, even as large as 1 centimetre in diameter at a depth of 10 centimetres, would show an increase of a fraction of a millimetre—too small to measure with accuracy, even if it could be clearly demarcated through the penumbra produced.

by the superimposition of shadows. The lateral tube-shift method gives an image which is the same for large and small objects, and the shadows overlap for only part of their extent, so that they can usually be clearly distinguished and accurately measured. It thus appears that Dr. Cave's method does not compare favourably with the common methods of depth location, and now its special claims in obstetrics require some comment.

The practice of pelvimetry differs in no way from the depth measurements carried out above, and with a lateral tube shift the distance of the brim from the film can be determined and the pelvic measurements, as recorded on the film, corrected by simple triangulation, as described by Hastings. This calculation can, of course, be avoided altogether by the use of a direct measuring method such as with the Thoms grid, which is exposed on to the film from the same level as the brim, but, owing to the uncertainty of definition of the brim level, the tube-shift method gives rather more accurate results. Dr. Cave's method would presumably give results as good as any other in this instance, but it must be pointed out that very heavy exposures are required in any case for pelvimetry radiographs, and a really enormous exposure must be required for his distant tube position.

In the case of cephalometry, however, his method is liable to serious error, which may give dangerously misleading results. The lateral tube-shift method is successfully used in this investigation, but is also liable to a certain degree of error, as the object is large and its size must be considered in three dimensions. This means that the shadows cast in the two positions of the tube are not cast by the same diameter, and so triangulation rules do not strictly apply, but the error is small and is usually ignored. In the vertical tube-shift method, however, the two shadows are cast by completely different diameters, as shown in the diagram, and calculations based on these measurements will make the object appear to be further from the film, and will lead to an estimate of the diameter of the head which is too small—a most vital error.

My conclusions are that the method is not new, that it is inefficient in general use, and dangerous in cephalometry.—I am, etc.,

Hove.

E. MILLINGTON, D.M.R.

Fracture-dislocations of the Spine

STR.—Mr. A. H. G. Munro has had a very wide experience in the treatment of fracture-dislocations of the spine, and his comments (Aug. 21, p. 246) are consequently of much interest. He apparently does not agree with the pessimistic view that cases of cord injury with complete loss of function lasting twenty-four hours are permanently complete lesions, and it is to be hoped that he is right. In my paper I was not quite so dogmatic as he seems to think, and I suspect that he has been misled by a mere synopsis. The number of cases was relatively small—21 cord and cauda equina lesions—and I went no further than saying that my series supported this pessimistic view—a view held by Sargent and Trotter, and, more recently, Naffziger, among other distinguished observers. Furthermore, the case Mr. Munro cites in support of his own more optimistic view is not of the type to which I was referring; the cord lesion was incomplete on admission, and only progressed later to a complete loss of function. In such cases it is generally agreed that there is a possibility of recovery, but this is a very different matter from the patient with complete loss of function immediately after the accident, and it is to this type I referred.

As regards frequency of locking of articular facets, my figures, though small, agree with those of Mr. Munro: of twelve cases with dislocation, locking was present in seven. Mr. Munro, in a large series of operations, has found internal fixation unnecessary. It should, however, be realized that at operation the processes do not just snap back into place with immediate stability resulting. There is a marked tendency to re-displacement, which can sometimes only be overcome by extreme hyperextension. In one case operated on by Mr. Sloan Robertson deep respiration was sufficient to cause re-dislocation, and to overcome this the spinous processes were drilled and fixed together by stainless steel wire. Subsequently I have done the same in two cases, and, in my opinion, this relatively simple procedure is well worth doing to ensure maintenance of reduction until the hyperextension plaster is applied. In the cervical region I would go further and say that there are cases in which it is impossible to maintain reduction without some form of internal fixation.—I am, etc.,

Ramsgate Hospital, Inverness.

R. C. MURRAY.

Skin Sensitivity to Sulphonamides

STR.—During the past two months I have seen several cases of cutaneous hypersensitivity to sulphonamides of the type reported by Park (July 17, p. 69). In general, whatever the route of administration of the sulphonamide, the eruption was almost confined to the head and neck, and the hands, especially the dorsal surface—i.e., the parts exposed to light. The lesions consisted of erythema, papules, with much exudation, and often on the hands bullae and pustules. Three-quarters of my cases were in markedly seborrhoeic subjects, and were followed by much desquamation and dryness of the skin. Other features not mentioned by Park I have noticed are oedema of the eyelids in every case, and conjunctivitis in two cases. A case was recorded in the *Journal* of April 3, 1943, of this sensitivity persisting for fifteen months. One of my cases, however, had a similar reaction two years previously, so there seems to be no time limit to it, and it may well persist throughout life without desensitization. One severe case, which also developed pyrexia, showed a strongly positive scratch test, with erythema and vesicles, when performed on the forehead.—I am, etc.,

London.

C. D. CALNAN.

Sulphonamides in Asthma

STR.—Your issue of May 1 has just come to hand, and in it I note with considerable interest the letter of D. K. O'Donovan recommending sulphonamides in asthma (p. 551). The use of sulphapyridine in old asthmatics associated with chronic bronchitis and emphysema has been standard practice in my medical wards for the past two years. The results, although not constant, have usually been surprisingly good, and this has been attributed to the occurrence of bouts of low-grade bronchopneumonia in these cases. These bouts are considered to precipitate the attacks of asthma, and sulphapyridine successfully combats them. At first the use of this drug was confined to those cases showing fever with or without leucocytosis. In this type of case the results have been consistently good. More recently this treatment has been tried in cases of asthma without fever, but in these patients the response has been more irregular, as is to be expected. It might further be pointed out that in certain areas of the Indian Decan patients suffering from chronic bronchitis with asthma and emphysema are common, particularly during the monsoon and the cold seasons of the year. Chronic upper respiratory infection is almost invariably associated in them.—I am, etc.,

Miraj, India.

L. B. CARRUTHERS.

Boiled Milk and Raw Protein

STR.—One does not wish to return the boiled milk discussion to your overworked staff and correspondence columns. But as reported in the *Journal* (Aug. 21, p. 251), a statement is made, quoted from Lord Horder in Parliament, about milk which rather upsets people who are trying to rear other people's babies on something other than their natural food. The report states, "Boiling definitely lowered its nutritive value." Admittedly the words are taken alone and out of context. Looking up my most recent book on children's diseases (*Sick Children*, Donald Patterson, 1937) it is stated as one of the advantages of boiled cows' milk that it is more digestible. Granted that this is not a comparison with pasteurized milk, but it is in agreement with the generally accepted opinion of civilized races that cooked foods, apart from fruit and certain fresh vegetables, are best. Should milk be exempted from this general rule that what one may call animal foods are best cooked? (I do not, of course, mean food fed to animals, but my composition has always been poor.) This statement that milk loses something by boiling is widely prevalent. Now backed by a statement in Parliament by Lord Horder, humble G.P.s such as I will have the greatest difficulty in controverting it.

Are any controlled experiments reported which show that babies fed on raw cows' milk thrive better, and that babies fed on pasteurized milk thrive better, than babies fed on milk just brought to the boil—which is my definition of boiled milk? And by this question I mean to include children arriving at school age. If such experimental evidence is available, I have not yet run across it. When the baby is weaned from milk and goes on a mixed diet should we continue the practice of

giving raw foods such as raw fish, to which certain Oriental races are said to be partial, or raw meat, in which certain African races are said to indulge? And if we continued the practice of giving raw animal proteins to human children after weaning, would these be more advanced at school age? We know the advantages given in the textbooks of cooking animal proteins, but, apart from the risk of infection by various parasites, I do not know of any controlled experiments either. Is there such a radical change in human babies that up to ten months they thrive best on raw foods, and immediately begin to thrive best on cooked foods thereafter? Practically, raw milk protein is the only animal protein which we do not cook. We cannot all afford oysters. One does not know of any experiments on human babies which clearly indicate that they might not thrive best on cooked human milk.

Whether the statement is made in Parliament by dignitaries of the medical profession or by anyone else, one can only decide that the statement that milk loses something by cooking—that is, something that is not counteracted by a corresponding gain—must be looked on as pure superstition.

Meantime, I have to begin all over again, arguing with distracted mothers who have failed to pacify a baby with several sorts of patent foods, and who assuredly, when boiled cows' milk is suggested, will triumphantly tell me that Lord Horder agrees with them, that boiling milk removes some spiritual essence which babies need—forgetting that all the patent foods they have tried are already well cooked.

Later on, when we tell mothers to be sure to cook fish and meat for toddlers, as well as most vegetables, will we be "stigmatizing and sabotaging basic foods"? There does seem to be a lack of logic somewhere. And logic still exists, in spite of Stuart Chase and others.—I am, etc.,

W. L. ENGLISH.

* We give the following quotation from *The Pasteurization of Milk*, by G. S. Wilson (Edward Arnold and Co.). "Where this [i.e., pasteurization] is impracticable, as in the home, the milk can be brought rapidly to the boil in a water-jacketed saucepan fitted with a lid to prevent scum formation, and, unless it is to be drunk immediately, cooled at once to as low a temperature as possible so as to interfere with the growth of any non-pathogenic organisms that may have survived." To quote Prof. Wilson again: "If neither Pasteurized nor Tuberculin Tested milk can be obtained, then the milk should be boiled, or dried milk made up with some suitable flavouring agent should be supplied."—Ed., B.M.J.

The Government's Milk Policy

SIR.—Milk is not necessarily safe because it has been pasteurized. Samples of pasteurized milk taken by me to the Emergency Public Health Laboratory in the unopened bottles as delivered were found to contain:

Lab. Ref. No.	Q 755—B. coli in 3 out of 3 tubes inoculated with 1/100 ml.
" " "	S.740 " " " 3 " 3 " " "
" " "	V.629 " " " 2 " 3 " " "
" " "	V.627—Plate count 140,000

The bottler as well as the milker may have dirty hands or a throat infection capable of contaminating the milk after it has been pasteurized. I am quite certain that para. 28 of the Milk and Dairies Order is not strictly observed. I have taken rinsings (*Practical Public Health Problems*, Sir W. Savage, p. 88) from several churns and bottles said to be sterile and ready to be refilled and found them to be contaminated. I find every person who handles the milk as a potential source of pollution.—I am, etc.,

E. J. CROSS,
Medical Officer of Health.

St. Neots.

Medical Boarding for the Merchant Navy

SIR.—Dr. S. H. Waddy's able letter (Aug. 21, p. 248) raises a most important point. It passes comprehension how our mercantile marine can go on year after year without any medical organization. The Shipping Federation has shirked its responsibilities in this matter, which is not so necessary for all those vessels that have competent ship surgeons, but for the many ships that have no medical personnel the need for shore overhaul of sailors is very urgent. Grade IV men with such disabilities as fits, diabetes, tuberculosis of the lung,

hernia, duodenal ulcer, and venereal disease can put to sea as easily as Grade I men.

The Board of Trade pays attention to food, sanitation, and accommodation, but has no system of medical examination. A sailor may pass a good deal of his time at sea unfit for duty on account of illness, then go ashore, be patched up temporarily, and ship again: he may also mangle at will.

The last paragraph of Dr. Waddy's letter is on the right line and should receive official attention without delay. Advantage could be taken of the medical recruiting boards throughout the country to examine all seamen for the Merchant Navy in order to start the scheme without delay. As rightly said, this is really a Government responsibility, and after the war it will be to the benefit of all concerned if the same system is carried on.—I am, etc.,

GEORGE DOUGLAS GRAY.

SIR.—Dr. Waddy's letter draws attention to one of the deficiencies in the present method of medical examination of merchant seamen, but it is hardly fair to the men to suggest that they are all malingerers.

In the past men have become seamen from choice. The medical standards have been lax and in certain branches of the trade non-existent, so that many men have been at sea for half their lifetime without medical examination. The doctor appointed by the Shipping Federation has time to make only a cursory examination and, it must be remembered, is employed by the owners to exclude the men who are unfit. It is no part of the examining doctor's duty to provide treatment or advice, and he functions as a one-man medical board. Nevertheless the standard of work is fairly high, and the number of men whom the doctor wrongly passes as fit will be found to be small. On the other hand, the power to mark a man as permanently unfit for service at sea also rests with the examining doctor, and this arbitrary power, which deprives the man for ever of his livelihood, is frequently used.

Many of the men now serving at sea have only returned to their calling since the beginning of the war, and their standard of physical fitness may well have been impaired by long years of unemployment. They may easily pass a medical examination without possessing the necessary stamina to stand up to life in the fore-castle under black-out conditions for the long voyages which are nowadays so common. These men receive none of the physical training which is considered necessary in the fighting Services, and, with the exception of some of the better companies, do not have the benefit of any of the prophylactic measures which should be available.

The Merchant Navy requires a real health service so that in future fit men are taken into a service which will take pride in keeping them fit. Dental caries and dyspepsia are two of the commonest complaints among seamen, and there is an obvious association between the two. The Seamen's Hospital Society provides in London much of the necessary service, but of all our other great ports only Cardiff has a special seamen's hospital.

Our seamen are entitled to something better than a further strengthening of the means of depriving them of their right to follow their calling, and reform, when it comes, will need to be on a grand scale. Victuals, living conditions, recreation rooms, bathrooms, and toilets will have to take their place alongside protective inoculations and vitamin concentrates to make the work of the medical boards a mere formality. "Shirking" and "loafing" are mean terms to apply without reservation to a body of men who have followed so faithfully one of the most dangerous callings.—I am, etc.,

London, W.1.

ALEC WINGFIELD.

British Spas

SIR.—The various Government Departments appear to have done everything possible to kill the work of the British spas. They have commandeered practically all the accommodation for offices, Government officials, civil servants, etc. The Ministry of Labour has depleted the trained staffs of the bathing establishments and spa hospitals in spite of urgent appeals to it and to the Ministry of Health. One skilled masseur, who has had over 15 years' experience, has been placed in the N.F.S., where he is employed in massaging the brasswork of the fire engines; this man has now been released. Another man,

fully qualified in wet and dry massage, has been placed in the R.A.F. as a hospital orderly, but is not employed in massage, as only women are so employed in that Force. Again, the authorities of the E.M.S. and the Ministry of Pensions do not officially approve of spa treatment, but concede its usefulness for civilians. The spa hospitals with their depleted staffs are working to capacity and are treating miners, munition workers, etc., and are returning quite two-thirds of them to work.

Those of us who have long experience of spa treatment recognize, as the Soviet medical authorities do, that more is required than physical treatment by massage, diathermy, and other forms of electrical treatment. There is a danger in this country that physical treatment will mainly consist in such, and ignore the great usefulness of balneological and hydrological methods. On this point it is observed that the Supplementary Report of the Council of the B.M.A. draws the attention of the teaching bodies of our medical schools to the necessity for instruction in physical medicine, and points out that in many of the smaller towns neither the facilities nor the trained personnel are available; "the result is that a considerable proportion of patients treated at spa hospitals suffer from disabilities which might have been cured or arrested at home."

A great opportunity is being lost by our Government. In pre-war days thousands of pounds went out of the country annually owing to British people frequenting the Continental spas. Even if the war stopped to-morrow it would take months to renovate the hotels and get them in working order. There are hundreds of people waiting to have a cure who cannot get accommodation of any sort—hard-worked officials, munition workers, people who have contracted rheumatism from sleeping in damp underground shelters, men and women who have been invalidated out of the Services, etc. This is an overcrowded and industrial island and no provision is made for health and rest centres for our people such as are found in Sweden and Russia. Discussions on health services, a State Medical Service, and the medical views expressed in the Beveridge report quite ignore this important point, and none of the discussions gets down to what is so urgently required in this country, and when the opportunity is so great for the Ministry of Health to embark on a comprehensive scheme which would produce so much benefit for the many.

Space will not allow me to enlarge on what is required. Town planning of spas, the elimination of all factories within a certain radius of the spa, large open spaces with numerous sun traps, the by-passing of all main through traffic, rehabilitation centres with occupational therapy; means of exercise, such as golf, tennis, bowls; etc.; psychological therapy, consisting of music, the drama, exhibitions of the arts, etc. Further, we should copy the Russians by having home farms attached to sanatoria, hostels, etc., providing them direct with fresh vegetables and pure milk.—I am, etc.,

HARROGATE.

G. L. KERR PRINGLE.

Learning the Art of Medicine

SIR,—I was most interested in Dr. D. W. Winnicott's letter (Aug. 21, p. 243) and agree with him. He points out that our professional work is partly science and partly art, and that if we have a State Medical Service the science may increase but the art will decrease, and the flood-gates will open wide to quackery. For there can be little doubt that the public at large suspects and fears our science.

The trouble begins with our education. We have gradually evolved from the necessity for Latin and Greek, and, in my opinion, it is time we evolved from chemistry, physics, and biology beyond the School Certificate standard. Few of us know the chemical composition or the number of grains—or is it grammes?—in a couple of tablets of sulphapyridine. It does not need a highly skilled chemist to prescribe a couple of aspirins for a headache. If this seems a sweeping statement I invite your readers to look at the physics papers set at the last First M.B. examination of London University. I would bet a lot that not a single practising medical man could pass, and that few indeed could give even a reasonable answer to a single question.

The inevitable evolutionary changes in our education must be cut out that which is useless (the present First M.B. as a start) and substitute that which is useful. In my opinion it is essential that the art must be taught and learned, and the

best way of doing this is to make each student do a year in general practice as part of his course.

I do not think it is yet appreciated sufficiently that the bulk of the work of the medical profession—the handling of the patient through his bodily and mental troubles—is done by general practitioners. Surely it is high time that the members who know the work that has to be done should have a larger control of the education of our students and a larger control of the profession itself in matters of policy.—I am, etc.,

ROTHEHAM.

ERIC COLDREY.

* Perhaps we may anticipate some comments on Dr. Coldrey's letter by remarking that a good general education and a grounding in the discipline of the basic sciences are not useless lumber in the practising doctor's mind, even if details learnt in classroom and laboratory are forgotten.—ED., B.M.J.

London Teaching Hospitals Committee

SIR,—A committee consisting of two representatives of the medical committees of each of the London undergraduate teaching hospitals has been formed with the object of co-ordinating the views of the medical staff of these hospitals at the present time.

At a meeting on Aug. 17 the following resolution was passed, and we have been asked to bring it to your notice with a request that you may publish it:

"This meeting regards it as essential that freedom of expression in medical matters and hospital policy and freedom of medical practice be preserved in hospitals in any post-war reconstruction; and that a medical committee should be the advisory body to the Governors of an institution on medical matters."

—We are, etc.,

GEOFFREY BOURNE, M.D., F.R.C.P.,
St. Bartholomew's Hospital, Chairman.
W. D. DOHERTY, M.CH., F.R.C.S.,
Guy's Hospital, Hon. Secretary.

London.

Psychiatry in General Hospitals

SIR,—While no unqualified affirmative can, of course, be given in reply to Dr. G. L. Alexander's invidious question (Aug. 14, p. 214), a categorical negative would do less than justice in view of the greatly varying nature of cases treated in our mental hospitals to-day. Moreover, there are many physical illnesses which would equally give cause for hesitation in similar circumstances because of their potentially disabling or propagational risks.

It seems pertinent to ask why, throughout the ages, disorders of the mind have, unlike most other varieties of human affliction, been singled out for social condemnation, since herein lies the meaning of that enlightenment to which we refer. The persistence of a stigmatizing attitude, even among some who might be expected to know better, is but an attenuation and modification of that attitude which in former days prompted punitive measures, such as the use of chains or corporal punishment, as appropriate treatment for the disordered mind.

The motive underlying this attitude in people otherwise not unkindly consists of a latent fear of their own unconscious forces; it is a projection of individual inherent anti-social tendencies, which, lying dormant in us all, have become manifest in the mentally disordered. Owing to the fact that the repression of these tendencies was in the first instance moralistically achieved, all subsequent lapses, irrespective of how caused, are viewed with condemnation—i.e., they become socially taboo. From various causes, many entirely physical in character, failure of repression may occur; thus it is to be found as the result of the toxæmias of pregnancy, in thyrotoxicosis, or yet again in the delirium of any acute infective disease. In the Hughlings Jackson sense, such manifestations, although psychically displayed, represent, at least temporarily, a lowering of the level of cortical physiological control.

The stigmatization of the disorders of mind, even in their minor manifestations (the so-called nervous breakdown is regarded with but veiled contempt), represents in fact an attempt to reinforce one's own repressions by condemning such untoward tendencies as may appear in others. This fear

of contagion and dim consciousness of personal susceptibility is readily rationalized so as to dispose of what otherwise would appear an unjust attitude. The remedy for the individual lies in his coming to terms with his own unconscious tendencies—an ideal only possible by the Freudian psycho-analytical approach. For the public in general, much yet can be hoped from their continued education as to the nature of mental disorder. This act of social justice can best be furthered by our great body of general practitioners, many of whom we know are already aware of the fundamental need for an attitude of scientific objectivity towards the problems of psychiatry.—I am, etc.,

Warrington Park Hospital.

W. H. SHEPLEY.

Health and Social Medicine

SIR.—The sudden attack of modesty by which the spokesmen of the profession have recently been overwhelmed is not without its comic side. We all agree, I hope, that the labourer who puts in the sewers has just as important a place in the social structure as the doctor, but even the least well instructed member of the populace to which Dr. W. N. Leak refers in his letter (Aug. 21, p. 243) will hardly fail to see the motives underlying the attempt by the profession to underrate its own importance and to stress instead the necessity for environmental reform.

Unfortunately, even if a Utopian state of affairs could be reached to-morrow in matters of housing, nutrition, and general standard of living, there would still be need for an efficient curative service for a long time to come. Cities are not rebuilt in a day. We have been officially warned that we shall be short of food for some years after the war. Devastated Europe constitutes a reservoir of disease which may well spill over and threaten the health of these islands. The incidence of tuberculosis and venereal disease is still rising. Further, when our main Forces are engaged on the Continent the resultant heavy casualties will leave a heavy burden of chronic traumatic conditions.

It is idle under these circumstances to belittle the importance of the curative services. If the doctor has at his disposal all the resources of modern medical science there are a few diseases which he can actually cure, there are many patients whose condition he can improve, and few who cannot be given a little help, even if it is only a little elementary psychotherapy. Dr. Leak's poor opinion of the capabilities of the doctor is surely an indictment of medical practice as at present constituted.

The populace may be ill informed on the finer points of medical science, but they are well informed as to the difficulties of getting adequate medical treatment to-day. They are all ex-patients or potential patients. If doctors when ill were compelled to seek treatment on the same terms as their patients they would lead the "ill-instructed clamour" for reform which Dr. Leak condemns.—I am, etc.,

St. Mary Cray, Kent.

BRIAN H. KIRMAN.

The Future Health Services

SIR.—Dr. J. Shackleton Bailey's letter (Aug. 7, p. 181) makes sad reading because it betrays, so obviously sincerely and with such placid and complacent politico-acquiescence, a state of mind which views without the slightest disturbance, indeed with an almost gleeful anticipation, the possibility of an immediate upheaval which cannot but result in the permanent and disastrous lowering of the status of our profession. "Immediate," because he says that both "inside and outside the House of Commons there is a highly critical consensus of opinion impatiently waiting for action." Medicine is by far the most "learned" profession in the world as practised even by the average doctor. The lawyer deals in printed word, in precedent, in tomes replete with ancient legal pronouncements and decisions, in argument; the clergyman in Holy Writ and the lessons to be drawn from it, in sermons and exhortations, in hymns and prayers and psalms. But the doctor cannot get away with either knowledge of books and power of clever and convincing argument or with profound knowledge of the Bible and a capacity to influence men's souls for good. After six years of the most exacting scientific study demanded of any profession, he has to graft on to this a far more profound

knowledge of, and insight into, humanity, both bodily and mental, than is called for in any other calling, or trade, or that matter.

So far as I have been able to gather in conversation a correspondence, certainly not less than 95% of my colleagues fairly representative of the profession as a whole, totally agree with the attitude of the politico-acquiescents as defined by Dr. Shackleton Bailey. It is impossible to drag on a highly specialized and individualistic body into turning themselves into a Government Department such as the P. O. Office, or one with the routine-bound, clock-watching, "drinking proclivities of Whitehall." Of all human activities medicine is the one that it is most important to keep free all except the minimum of political and Government interference. Far from being "the strongest trade union in the world," as someone has quite erroneously stated, doctors equipped neither psychologically nor occupationally for combination and resistance, and if on a vote-catching campaign any Government tries and succeeds in establishing the impossible—i.e., the regimentation adumbrated by your correspondent—then the entire status of the profession will infallibly be lowered because a different type of person will begin to enter it. Indeed, it may well happen that the supply of students will fall perilously low if a Government appointment, with accompanying loss of initiative, freedom, and incentive to study, all they have to look forward to after six years of intense study punctuated every few months by formidable examination hurdles to be leaped.

Dr. Bailey deprecates "delay pending demobilization." It is difficult to conceive why. The older or unfit civilian doctors are too busy to combine, arm, and resist political cajolery and pressure. The younger fit men in the Services have the chance. It is manifestly unfair, though it may be go "policy," for Parliament to charge in with their tanks at the weakest spot at this juncture, with half the profession absent and unconsulted, and the other half unholidayed and unsuited trying their utmost to keep the medical home-front from burning.

I note that Dr. Shackleton Bailey is, like myself, a (Government) Factory Act surgeon. He therefore has to fill up a form showing that he has carried out the following examination of each young person joining a factory: "Any previous employment (Name of Employer and Character of Employment), Name and Address of Health Insurance Practitioner, Address of last School, Medical History and Information obtained from School Medical Record, Bodily Development and Nutrition, Height, Weight, Skin and Hair, Eyes and Eyelids (Right, Left for vision), Mouth and Teeth, Nose, Throat, Ears, Glands, Respiratory System, Circulatory System, Nervous System, Bones and Joints, Other Observations"—and sign it. The capital letters are all the Government's, and the fee for this detailed overhaul, which, except for urine examination and blood pressure, practically amounts to a life insurance requirement, is 2s. 6d. This is a sample of Governmental valuation of our professional services now, and with a vivid recollection of the happenings of 1912 in mind I have no reason whatever to suppose that this valuation will not permeate any State service that is instituted in the future. The tragedy of it (and it is difficult to understand why the "reformers" do not visualize this) that if it is pushed through, it will be the public and not the pigeon-holed doctors, cribbed, cabined, and confined, who will be the first to complain. But then it will be too late.—I am, etc.,

Stowmarket.

H. S. GASKELL.

Plant Hormones

SIR.—The annotation on plant hormones (Aug. 7, p. 17) states that plant hormones are "particularly active in stimulating root growth." As it stands this is misleading. The auxins, as Went and many other workers have demonstrated, may promote growth in one part of the plant and inhibit in another. Prof. Kögl and his collaborators, who first isolated indole-3-acetic acid from urine, actually demonstrated the inhibitory effect on the growth in length of Avena roots when they were immersed in solutions of indole-3-acetic acid at auxins "a" and "b." Writing on the inhibition of root growth by auxins Bonner and Koepfli compare the growth-inhibiting activity of twenty-one analogues of indole-3-acetic

id, and regard the chemical specificity of auxin for root growth closely similar to the chemical specificity for shoot growth, the substances being highly active in promoting growth in roots and inhibiting roots.

In experiments which I have carried out with seedlings this opposite effect of auxin on the growth of root and shoot is early demonstrated. Application of auxin may cause swelling of a stem or root. It may stimulate cell division and initiate the growth of adventitious roots on stem cuttings. It also inhibits the growth of lateral buds when applied to the main stem. Thus, to quote Went,⁴ "one substance may be promoting growth in one part of the plant and inhibiting it in another."—I am, etc.,

Reading.

Simmonds's Cachexia

SIR.—I am in the midst of some research work on a rare endocrinological syndrome—namely, Simmonds's cachexia—and should be extremely obliged to hear from any doctor in regard to a patient suffering from this disorder who is willing to come into hospital for two or three weeks for investigation and treatment.

I would not venture to presume upon the hospitality of your correspondence columns were not the disorder of such comparative rarity.—I am, etc.,

London, W.1.

S. L. SIMPSON.

National Health Insurance and Assumption B

SIR.—National Health Insurance at its inception in 1911 represented a great contribution to the social services of this country, placing a medical service at the disposal of sections of the community which found difficulty in obtaining it themselves. Few will question this statement, but does N.H.I. provide a framework into which the medical services of the future can be fitted? Has the time not come when N.H.I. organizational forms represent a brake on progress rather than a spur thereto?

Consideration of this question is very important at the moment, especially in view of Recommendation M of the Council of the B.M.A. (*Supplement*, Aug. 7, p. 20), which suggests that implementation of Beveridge's Assumption B would, for the moment, be met by a two-way extension of N.H.I. The following points may help in considering these questions.

(a) N.H.I. is based on the individual practitioner with his own professional equipment, accommodation, etc. (This statement is not, in general, invalidated by the development of partnerships.) It is impossible within its forms to develop that co-operative team work which is demanded by the increasing technical complexity of medicine and its allied services.

(b) N.H.I. tends to degrade the general practitioner into a mere sifter of cases, unable to devote a sufficient time to their consideration because of the numbers to be seen under the conditions it imposes. As he has to provide a 24-hour service, seven days a week, with little possibility of any private or social life outside his professional work, his chances of putting into practice those clinical ideals he had on leaving his medical school are slight indeed. Preventive medicine and research work in his own sphere of activity are closed to him. His growth to that full clinical stature and position which are rightly his because of the importance of his position *vis-à-vis* his patient is inhibited by his working conditions. To say so is in no sense to criticize the body of insurance practitioners, which gives loyal and devoted service; it is to criticize the system under which these doctors work.

(c) A two-way extension of N.H.I. cannot solve any of these problems. On the contrary, it will aggravate them and at the same time strengthen the position of the approved societies, with consequent economic loss to patient, doctor, and national health. What the public needs is a health service maintained

by a completely unified profession, operating as a single instrument to bring every aspect of scientific medicine within the reach of every member of the community. The profession on its side needs an organization that will enable its members to produce their best clinical work in the best conditions—good income, reasonable hours of work, holidays, pensions, modern professional accommodation, adequate equipment, lay assistance that will relieve practitioners of non-clinical work, and the possibility of living "privately."

(d) To extend and develop N.H.I. is to push further away into the distant future these desirable and necessary improvements. That will be the result of carrying Recommendation M, which represents a "slipping back" from the decisions on group practice made at last year's Annual Representative Meeting, and a definite retreat from Assumption B.—We are, etc.,

The Doctor with a Cold

SIR.—Whatever scheme may be evolved for the betterment of the medical services of the country, it must not be forgotten that it will depend for its success entirely on the good will of the doctors, especially for the next ten to fifteen years.

Now, according to the Press, in the years before the war workers were advised, at the onset of influenza or febrile cold, to stop work and go to bed, and further reports of the large percentages of absentees showed that the advice was taken. Doctors, it also said, were working all hours of the day and night. A matter not brought to prominence was that many of the doctors were suffering likewise, and should also have been in bed. It will cause a sense of grievance if doctors, as modified or wholly civil servants, are supposed to be the only workers not allowed to go sick. Such sickness takes place mostly at one period of the year, and simultaneously over the country, and means that a very large pool of doctors must be built up to carry on the normal services. At present and for many years this will be impossible, and unless the doctor behaves as he has always done, and works on while others go to bed, the whole scheme will fail.

This fact, if stressed, may modify the increasingly dictatorial attitude of the Ministry of Health, either by force or, preferably, by a realization of the debt owed to doctors, and that if their work in helping to tide over a very difficult transition period is to be free of all grievance, adequate pay and privileges must be given them.—I am, etc.,

Hove.

FRANK PORTAS, M.D.

Appeal for Back Numbers

SIR.—There must be many who are responding to the appeal for back numbers of the *Journal*, and I am going to suggest that they should do what I have already arranged for in my own case—namely, ask that the postage fees (which are offered to be refunded) should be allowed to accumulate until the end of the financial year and then handed over to the Central Charities Fund.

Few or none would miss the 6d. or 9d. paid for postage occasionally, but these small sums, multiplied many times over, would mean a quite appreciable addition to our Charities Fund at the end of a year.

May I commend the idea to my fellow-members.—I am, etc.,

Stokesby, Gt. Yarmouth.

PERCY B. SPURGIN.

According to the statistics of the health authorities (*Nationaltidende*, July 11, 1943), the mortality rate in Denmark for 1942 was 9.6%. In that year there were 2,200 fewer deaths than in 1941. Infant mortality and mortality of elderly people have decreased. Infant mortality was 4.7% as against 5.5% in 1941. The age groups between 17 and 45 have an increased mortality. Deaths from infectious diseases and from pneumonia have greatly decreased. This is attributed to sulphonamide therapy. There is an increase in cancer deaths, especially in women. There has also been an increase in the number of murders (36 in 1942).

Obituary

SIR FRANCIS FREMANTLE, M.P.,
D.M., M.Ch., F.R.C.P., F.R.C.S.

The medical men in Parliament who were returned after each of the half-dozen general elections between the two wars formed a varying group, in numbers (ranging from ten to twenty), in political affinities, and in the interest they took in medico-political affairs. But there was among them all the time one constantly dependable figure, Sir Francis Fremantle,

whose death on Aug. 26 we chronicle with great regret. From 1919 onwards he was the most thorough example of "The Doctor in Parliament," to quote the title of a lecture he once gave under the Chadwick Trust, always diligent and interested, with a high conception of the function of the medical man in the shaping of legislation and criticism of administration. No one recognized more fully that the first responsibility of the medical man in Parliament is to his constituents, not to his profession, but subject to this he was ready to respond to any call made upon him to assist public health and the causes

which the medical profession had at heart. He took his Parliamentary duties, like everything else, with great seriousness. Having already had a career in public health before he entered Parliament he felt himself, as indeed he was, well qualified to speak on public health subjects, and in the chair of the Parliamentary Medical Committee, which he first occupied in 1922, and continued to hold save during the period of the Labour Governments—when a Labour chairman was elected—it was his task to interpret medical views to Parliament, and, what was equally important and perhaps still more difficult, to interpret Parliamentary procedure and party exigency to the medical profession. The British Medical Association, in common with a number of other bodies concerned with the health of the community, often had occasion to thank Sir Francis Fremantle for his work on their behalf in voicing in the Legislature the new outlook in medicine and sponsoring and supporting measures which the medical profession desired to see placed on the statute book, not to speak of such services as asking questions in the House or introducing deputations to Ministers.

Francis Edward Fremantle came of a family whose name is distinguished in naval annals. His great-grandfather, Francis Fremantle, commanded the *Neptune*, the second ship behind the *Victory* at Trafalgar. His grandfather, another Francis, was at one time Secretary for War, and lived to become "the father of the House of Lords" and the patriarch of Buckinghamshire society. His father, however, the Very Rev. and Hon. W. H. Fremantle, chose the Church, and eventually became a well-known Dean of Ripon. Francis was born on May 29, 1872. In 1886 he entered Eton as King's Scholar, where he remained for four years, and then went to Balliol College, Oxford, from 1891 to 1894, where he gained a reputation in athletics. In 1895 he began his medical training at Guy's Hospital, qualifying M.B., Ch.B. in 1898. In 1903 he became M.Ch. and Fellow of the Royal College of Surgeons, in 1910 Fellow of the Royal College of Physicians, and in 1928 took the D.M. of Oxford.

After holding a house-physicianship at Guy's he went out to the South African War as a civil surgeon with the field Force, afterwards collecting his military experiences in a book of nearly 600 pages entitled *A Doctor in Khaki*. On his return he served as assistant secretary to a War Office committee for the reorganization of the Army Medical Service. In 1902, in which year he took the D.P.H., he was appointed county medical officer for Hertfordshire, a county with which his

career, professional and Parliamentary, was henceforth to be closely bound. Through his mother he eventually inherited the seat at Bedwell Park, near Hatfield. Before he had really got into the saddle as county medical officer he was sent, in 1903, to the Punjab as plague medical officer, acquiring some very useful experience, and afterwards, in 1903-4, he acted as special correspondent for the *Lancet* in the Russo-Japanese War. In the war of 1914-18 Fremantle served as D.A.D.M.S. (Sanitary) in Mesopotamia, and he also saw service in Gallipoli and Egypt, and was mentioned in dispatches, retiring with the rank of lieutenant-colonel R.A.M.C. On his return he devoted himself to public affairs. He had relinquished in 1916 his post of county medical officer, though he continued to serve in an honorary consultant capacity. In 1919 he was elected to the London County Council and served for three years, being for part of the time chairman of the Housing Committee. In the same year he entered Parliament as a Conservative for the St. Albans Division, and retained the seat with very large majorities. Although always on good terms with his party, he was not a strong party man, and once he declared that dogma—meaning presumably political dogma—is of the devil, and that the solution of problems comes not by the application of rigid theory but by experience.

In everything that had to do with public health, especially on the side of housing, Francis Fremantle was prominent. In 1920-1 he became president of the Society of Medical Officers of Health. In 1923 he served on Lord Trevethin's Committee on Venereal Diseases. He was a fellow and vice-president of the Royal Sanitary Institute, to whose congresses he contributed many papers, and past-president of the Section of Epidemiology and State Medicine of the Royal Society of Medicine. In 1930 he was appointed a member of the Industrial Health Research Board. In 1922, and again in 1930, he served on the Rent Act Committee to advise the Government on the future of the Rent Restriction Act. He attached himself enthusiastically to the garden city movement, was chairman of council of the Garden Cities and Town Planning Association, and director of the Welwyn Garden City in his own county.

Although never closely identified with the central work of the B.M.A., he was always helpful on special committees. He was a member of the committee which prepared in 1924-5 the evidence to be given on behalf of the Association to the Royal Commission on the Insurance Acts. In 1922 at the Glasgow Meeting he was vice-president of the Section of Public Health, and in 1937 at Belfast vice-president of the Section of Medical Sociology. For some years he served on the Parliamentary Subcommittee and on the Central Emergency Committee. In 1938 he was one of four medical M.P.s who were specially invited to be present at the Annual Representative Meeting. In 1940 he was made a member of the Medical Planning Commission. His writings, in addition to *A Doctor in Khaki* already mentioned, included *Health and Empire*, published in 1911, and two books which were really companions, *The Housing of the Nation* and *The Health of the Nation*, both published in 1927, and both carrying a foreword by Mr. Neville Chamberlain—then Minister of Health. His *Health of the Nation* in particular was a most commendable work, and though not likely to have a popular appeal, it went into a second edition within a couple of years. In reply to one critic who said that the information it afforded on any one subject was better given in official publications, Fremantle said "Precisely; this book is a bait." But that was too modest an appraisal. It was, and remains, a useful work, the more so because he approached the subject of public health not as a branch of science but as a branch of civics.

In 1926 Fremantle was appointed Deputy Lieutenant for the County of Hertford, and in 1932 he received the honour of knighthood. He had been appointed O.B.E. in the Birthday Honours of 1919.

A. I. SIMEY, M.D., F.R.C.P.

Dr. A. I. Simey, who died at Fordingbridge on Aug. 20, was for 22 years medical officer to Rugby School, succeeding I. Clement Dukes, who had held that post for 37 years. Athelstane Iliff Simey was born at Sunderland in 1873 the son of Ralph Simey, J.P., D.L. He went to Rugby in 1887 where he won a classical scholarship, and entered King

College, Cambridge, with a classical scholarship in 1892; in 1895 he was placed in the first class of the Classical Tripos. After two further years at Cambridge as a natural science student he went to the London Hospital for his clinical course and qualified M.R.C.S., L.R.C.P. in 1901. He took the M.B., B.Ch. degrees in 1902 and the M.A. and M.D. in 1905, after serving as house-physician, house-surgeon, and medical registrar at the London Hospital. In 1906 he obtained the M.R.C.P. and for a short period was physician to out-patients at the Victoria Park Hospital for Diseases of the Chest. Then in 1908 he was appointed medical officer to his old school and went to live at Rugby. During the last war Simey held a temporary commission in the R.A.M.C. as M.O. to the Officers' Hospital at Le Havre. Apart from his duties at Rugby School he worked for many years on the staff of the Hospital of St. Cross as physician and medical officer in charge of the x-ray and skin departments. He joined the B.M.A. in 1910 and was a member of the Association of Physicians of Great Britain and Ireland. His election as F.R.C.P. came in 1925. Like his famous predecessor, Clement Dukes, Simey was a recognized authority on health at boarding schools, and wrote on the hygiene of adolescent boys, and on the medical supervision of camps, sports, and exercise. His hobby was natural history, and in particular botany and entomology.

R. H. writes:

I first met Simey at the London Hospital in 1900. He had then just come down from Cambridge, where he had taken a first in the Classical Tripos, and was now embarking with enthusiasm on the clinical course. I was early impressed not only by his intellectual ability but by the sincerity and modesty of his character, and our relation as teacher and pupil (we were almost of an age) soon grew into one of close friendship which lasted for life. After qualification he held some resident posts at the London, increasing both the general esteem in which he was held and his affection for the hospital and everyone connected with it. Soon afterwards he was appointed medical officer to his old school—Rugby—of which he was a devoted son. He carried out his duties there with the thoroughness and high conscientiousness which characterized all he did, and became recognized as a leading authority on the diseases of school life. On resigning his post at Rugby he went to Exeter as physician to the Royal Devon and Exeter Hospital, engaging also in consulting practice in the West Country. But it was not many years before he was struck down with sudden illness, and for the rest of his life he was more or less incapacitated. He spent it partly in the New Forest, to which he had been attracted by its facilities for his hobby of bird-study, and partly in his cottage in Cumberland, bearing his enforced inactivity with exemplary courage and cheerfulness, and supported by the devoted care of his wife. The end came quite peacefully. He died at dawn, and his last words were: "How wonderful! I do love the light"—for the beauties of Nature meant much to him always. He has left little record of his long experience as a school doctor, for although he had accumulated a mass of clinical data his high standard of accuracy and scientific scrupulousness made him reluctant to publish; but those who were privileged to know him intimately will always cherish his memory as that of a great gentleman and one who exemplified in all he did the highest standards of our profession.

J. C. M. writes:

It is only for a few recent years that I have had the privilege of knowing Dr. Simey and visiting him at his home on the edge of the New Forest, overlooking the valley of the Hampshire Avon. The thatched roof of his home is in keeping with its old-world cottage garden, which is at the same time a veritable museum of rare and interesting ferns, flowers, and shrubs which he collected and tended over many years; it is also a miniature sanctuary for the birds which Simey knew and loved so well. Dr. and Mrs. Simey had a genius for friendship, which had a fragrance that will endure in the hearts of all who enjoyed it. This was a feature of Simey's 22 years at Rugby School. I am told by one who knows that the boys loved him and welcomed admission to the "San" for the sheer joy of contact with him. He was indeed a "gentle doctor" and a gentle man.

CECIL PRICE-JONES, M.B.

We regret to announce the death on Aug. 27 of Dr. Cecil Price-Jones, the haematologist whose work on the size of blood cells made his name known in every civilized country.

He was born in 1863 son of Dr. William Price-Jones of Surbiton, whose practice he carried on for a time after graduating M.B.Lond. in 1889 from Guy's Hospital, where he won the Preliminary Science Exhibition in 1884 and was assistant to the bacteriologist. For some years he was M.O.H. under the Kingston-on-Thames rural sanitary authority, but his real bent was for research, and he devoted himself more and more to haemacytology. He won a Salters' Company scholarship in 1911 and was appointed assistant pathologist to the Middlesex Hospital Cancer Research Laboratory. Much of his later work was done at University College Hospital Medical School, where he was appointed Sidney Ringer lecturer in 1936. Price-Jones's classical work on sizes of blood cells received early encouragement from the British Medical Association, the Council making him two scientific grants—in 1909 and 1910. He had joined the B.M.A. in 1900 and was a member of the Pathological Society of Great Britain. During the last war he served with the British Expeditionary Force as a temporary captain in the R.A.M.C.

Cecil Price-Jones's *Blood Pictures*, first published in 1917, was a brief and clearly written introduction to clinical haematology, beginning with the technique of haemacytology and the normal blood picture and following with an account of the use of blood counts in the diagnosis of disease. In a small space it gave the maximum amount of information, and was accompanied by five admirable coloured plates, the whole providing an excellent guide to house-physicians and clinical clerks. A second edition was called for in 1920, and a third edition in 1933 brought the handbook up to date. The chapter on the measurement of the size of the red blood cells was illustrated by the graphic curves with which the author's name is rightly associated. He also contributed papers on his special subject to the *Journal of Pathology and Bacteriology*, and published in 1933 a monograph, *Red Blood Cell Diameters*, which gave a lucid account of long-continued and mathematically controlled work by himself and a review of the results obtained by others. Price-Jones had a concise way of writing, and for a number of years he gave valued help to this *Journal* by reviewing books on haematology.

To his friends Cecil Price-Jones was known as a connoisseur of life, with a dry humour all his own. He was a gifted musician and had much skill with brush and pencil. In his country home at Radlett, well named "The Apple Orchard," he cultivated his garden and cared for the fruit trees and their crop.

JOHN MURRAY, F.R.C.S.

An old house-surgeon of Mr. John Murray's, the first to serve for him when he became senior surgeon to Middlesex Hospital shortly after the last war, sends the following tribute as a supplement to that already paid him in the obituary notice which appeared in the *Journal* of Aug. 28.

John Murray had a strong personality and a conservative but essentially sound outlook, founded on a wealth of clinical experience. He had, in addition, a keen sense of humour, and a merry twinkle would appear in his eye when he gave his opinion, usually iconoclastic, on some new-fangled and often ill-established procedure. "Oh, I say, I say!" he was wont to remark. "You might as well stick a postage stamp on the sole of the foot." He was opposed to operation in acute pancreatitis, many cases of which he had seen, and when, occasionally to the astonishment of his colleagues, recovery took place following masterly inactivity, he would remark with a smile, "Another triumph of conservatism!" His hobbies were billiards and Freemasonry, and he achieved distinction in both, making breaks of over a century in the one, even against crack players, and reaching Grand rank and winning many honours in the other. He liked to compare operative surgery to the playing of billiards, remarking that to be adept at either you needed to be constantly practising it. Mr. Murray did not seek and, in fact, sometimes went out of his way to avoid private practice, but nothing was too much trouble for him with his hospital patients, and he would come round to Middlesex at any time of the day or night to do something for any one of them. He loved to have a dig at a friend, and I well remember how one day he was chuckling in high glee because he had said to a gynaecologist

whom he met on the way to the hospital, "You do glands in the neck, don't you?" and the gynaecologist had replied, "Oh, you heard about that case, did you?" As a member of the Court of Examiners he became known to many candidates. One day on returning from examining for the Fellowship he told how a candidate had flourished his knife about in the operative test. "You won't stick me, will you?" said Mr. Murray. "No, sir," said the astute candidate, "I remember last time." "What do you mean?" he was asked. "Well, sir," he replied, "last time you stuck me!" "I had to let him through," said his bluff but kind-hearted examiner, and added, "He knew his work." Passing this candidate seemed to give him especial pleasure, and perhaps this story best describes the man he was. Strong, perhaps rather bluff, no nonsense and straight as a gun barrel, he was a chief whom it was a privilege to serve. His high sense of professional integrity and kindness, even if somewhat hidden behind a rather severe and dignified exterior, will cause him to be long remembered with affection by Middlesex men.

The death took place at a nursing home on Aug. 7 of Dr. J. J. R. BINNIE of 21, Walker Street, Edinburgh. John James Rouse Binnie qualified M.B., Ch.B.Ed. in 1919, proceeding to the M.D. in 1921. In 1920 he took his D.P.H. after holding the post of medical superintendent of Lightburn Hospital, Shettleston, Glasgow. For a time he was in general practice in Mid-Calder. Later he returned to Edinburgh as consulting radiologist in succession to the late Dr. Hope Fowler, and in this capacity was attached to Gogarburn and Craiglockhart E.M.S. Hospital. Dr. Binnie held the rank of major in the last war, and also served in the present one until he was released owing to ill-health. In spite of this he continued to do good work for the Emergency Medical Service.

The death of Dr. H. CHISHOLM WILL, which occurred on Aug. 11, will cause great regret among his many friends in Bromley, Kent. Dr. Will served in the R.A.M.C. in France and Gallipoli from 1915 to 1918, and then settled in practice in Bromley, where he has practised for nearly 25 years. He was closely associated with the Bromley Congregational Church, of which he was a deacon for 21 years. He took an active interest in Congregational churches generally, and was a member of the executive of the London Congregational Union, a member of the executive of the Kent Congregational Association, and a delegate of the Bromley Church to the Congregational Union of England and Wales. He took a special interest also in the work of the London Missionary Society and of the Bromley Crusaders. Dr. Will, who qualified in 1893, was closely associated with the activities of the British Medical Association, which he joined in 1900. He was secretary of the Bromley Division for ten years (1922-32), and chairman from 1939 to 1941. On many occasions he acted as representative on the Representative Body, and even after the onset of his illness he attended meetings of the Association whenever he was able to do so.

The death has occurred in a Glasgow nursing home of Dr. JOHN AITKEN, aged 67. A native of Glasgow, John Aitken was educated at Garnethill School and Glasgow University, where he graduated M.B., Ch.B. in 1898 and M.D. in 1901, taking both with commendation. After a period as resident in the Western Infirmary and Royal Maternity Hospital he joined the Scottish Red Cross Hospital in the South African War as assistant physician, being mentioned in dispatches. Thereafter he succeeded the late Dr. Prentice in Kilmarnock, eventually becoming, to his undisguised satisfaction, physician to the Kilmarnock Infirmary. Here he practised for a quarter of a century, with an interlude when he was a medical officer to the 1st Division in Palestine in the last war. Following a breakdown in health he sought the sunny shores of the Mediterranean and built up a practice among the British colony at Allassio, returning to this country in 1940. Maintaining throughout a busy life an interest in the science of medicine, especially his first love, physiology, he was an early worker in haematology, among his publications being papers on pernicious anaemia and haematuria. Apart from service in the Territorials he had few outside interests, but acquired a taste for gardening, characteristically specializing in the viola, the touchstone of the Ayrshire amateur. He was a member of the B.M.A., and of the local panel committee, attending an occasional Panel Conference. He is survived by his widow, a daughter, and a son, a member of his own profession, at present on service in India. Of a sanguine temperament, buoyant and debonair, Aitken was ever a stimulus to his friends and quickly made his presence felt in any assemblage; but he will be remembered best for his exuberant spirit and alertness of mind and body, despite years of ill-health.

By the death of Col. Sir GEORGE HASTINGS, V.D., M.R.C.S., L.R.C.P., at the age of 90, the profession loses a personality of Victorian days the like of whom, it is safe to say, will not be seen again. To call him a Dickensian character, writes an old friend, might be very slightly to overstate the case, but at least he might have stepped from the pages of Mr. Sadler's *Fanny by Gaslight* or from a "conversation piece" canvas by his father-in-law, W. P. Frith. He reached the long-obsolete rank of surgeon colonel in the old Middlesex Yeomanry Cavalry—itsself a designation abandoned before the present century began—but was best known as the presiding genius, indeed dictator in all but the name, of the Ranelagh Club, where he was chairman for forty years. He was also president of the Coaching Club, of which he was the senior member. From all this it will be gathered that he was a horse-lover; certainly he dressed for the part—sponge-bag trousers, glossy top-hat, wash-leather gloves, large cravat, immaculate frock coat—and on the right occasions the correct black-banded grey "topper," as recorded in the *Times* recently. He was a West-End "society" practitioner of very long standing; and was also consultant to the Gas Light and Coke Company. He had his medical education at St. Bartholomew's Hospital, qualified M.R.C.S., L.R.C.P. in 1875, and served his own hospital as house-physician. He was the son of George Hastings of Terrington, Norfolk, and married Alice, daughter of Mr. W. P. Frith, R.A., by whom he had two daughters. He was knighted in 1910, was a Knight of Grace of the Order of St. John of Jerusalem, and held the Volunteer Decoration for his long service with the Yeomanry. Of late years he lived in the Albany, exactly his right milieu.

The following well-known medical men have died abroad: Dr. EDWARD JACKSON, formerly professor of ophthalmology in the University of Colorado, and consulting editor of the *American Journal of Ophthalmology*, aged 86; Dr. FRANK W. MARLOW, professor of ophthalmology for forty years at Syracuse University and member of the Ophthalmological Society of the United Kingdom, aged 84; Dr. LUTHER CROUSE PETER, emeritus professor of ophthalmology in the University of Pennsylvania, aged 73; Dr. GUSTAF NEANDER, pioneer in the campaign against tuberculosis in Sweden, aged 68; and Prof. EMILE SERGENT of Paris, the eminent authority on tuberculosis, aged 76.

Universities and Colleges

UNIVERSITY OF LONDON

The title of Reader in Medicine in the University of London, with the status and designation of appointed teacher, has been conferred on Dr. Clifford Wilson in respect of the post held by him at the London Hospital Medical College.

The reduction in the clinical course for the M.B., B.S. degrees will remain in force during the season 1943-4. The additional M.B., B.S. examination to be held in 1944 will begin on Monday, Jan. 31.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Prisoners of War.—War Subs. Capt. H. D. T. Gawn, R.A.M.C., Temp. Lieut.-Col. L. R. S. Macfarlane, R.A.M.C., War Subs. Capt. E. Snell, R.A.M.C.

Wounded.—War Subs. Capt. J. S. Montgomerie, R.A.M.C.

DEATHS IN THE SERVICES

It is now announced that Dr. JAMES RAWDON SODDY, aged 24, previously reported as missing, lost his life at sea by enemy action in July last. He qualified M.R.C.S., L.R.C.P. in 1942 from St. Thomas's Hospital and held house appointments at the Royal Portsmouth Hospital and the Lambeth Hospital. At the time of his death he was on the way to take up an appointment in the Colonial Medical Service in Nigeria.

Dr. VICTOR VARTAN MUIR of the Colonial Medical Service, Nigeria, is reported to have lost his life at sea in July as the result of enemy action. He graduated M.B., Ch.B. of Edinburgh University in 1939 and took the D.T.M.&H. a year later. His father is Dr. Ernest Muir, C.I.E., medical secretary of the British Empire Leprosy Relief Association and at present head of the Leprosarium in Trinidad.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week a rise was reported in notifications of whooping-cough 160, dysentery 49, and diphtheria 36, while there was a fall in those for measles 427, scarlet fever 42, and acute pneumonia 34. The increase in the figure for whooping-cough was due to a general rise throughout Yorks West Riding, 139 cases.

The fall in the number of cases of measles was most pronounced in the counties of Essex, Suffolk, and Norfolk, where the decreases were 51, 63, and 45 respectively. The incidence of this disease was highest in Kent 110, Lancashire 72, and London 53.

Relatively big increases in the number of cases of dysentery have been reported for the last three weeks, and the week's figure of 198 cases is the highest for almost a year. An outstanding feature is the 57 cases in Yorks West Riding, the chief outbreaks being in Wakefield C.B. 18, in Knaresborough U.D. 14, and in Wharfedale R.D. 15. Outbreaks occurred also in Kent, Malling R.D., 11; Wiltshire, Westbury U.D., 9; Suffolk, Debin R.D., 8; Hertfordshire, Watford M.B. (in the local isolation hospital), 8. There were 19 cases in London and 17 in Lancashire (Liverpool C.B. 10).

In Scotland there were 33 more cases of whooping-cough, but 11 fewer cases of dysentery, than in the preceding week. The incidence of dysentery is still high (89 cases), the chief centres being the cities of Aberdeen 20 and Glasgow 16, while Kincardine County had 12 cases.

In Northern Ireland further cases of typhoid were reported from the outbreak in Belfast; 14 diagnosed and 7 suspected cases are now in hospital.

The Week Ending August 28

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,890, whooping-cough 1,915, diphtheria 614, measles 986, acute pneumonia 337, cerebrospinal fever 48, dysentery 129, paratyphoid 7, typhoid 16.

Registrar-General's Quarterly Returns for Scotland

The chief feature of the returns for the second quarter of 1943 was the high birth rate of 20.4 per 1,000 of the population; this was the highest rate recorded in any June quarter since 1930. The infant mortality of 58 per 1,000 live births was 10 below the average of the five preceding second quarters. The number of stillbirths was equivalent to a rate of 34 per 1,000 total births. The maternal mortality of 3.5 per 1,000 total births was the lowest for any second quarter since 1931. A general death rate of 12.7 per 1,000 was recorded, this being 0.5 below the average of the five preceding June quarters. The death rate from all forms of tuberculosis was 66. Deaths from the principal epidemic diseases numbered 48 more than in the second quarter of 1942, but the rate (24 per 100,000 of the population) was 11 below the average of the second quarters of 1938-42. The diseases responsible for the largest number of deaths were: whooping-cough 77, influenza 73, diphtheria 51, cerebrospinal fever 44, and measles 41. Road accidents caused 182 deaths, 102 fewer than in the previous quarter. The marriage rate has almost returned to pre-war level, being 7.8 per 1,000, which is 2.0 below that for the corresponding quarter of 1942.

Paratyphoid in Schleswig-Holstein

A severe epidemic of paratyphoid broke out recently in the district of Husum in Schleswig-Holstein. The health authorities there issued a statement on the precautions to be taken by the local population as follows: (1) Milk should be quickly boiled and rapidly cooled. (2) Water from springs and ditches should be drunk only when boiled for tea or coffee. (3) Fruit and raw vegetables should be thoroughly washed with mains water or with boiled water. (4) After using the w.c. thoroughly wash the hands. (5) Always wash the hands before eating, including the breakfast meal. (6) Stop unnecessary shaking of hands. (7) Publicans must thoroughly wash glasses in running mains water or in boiled underground water which must be changed several times a day. (8) Ice firms must use only mains water or boiled spring water for making ice. (9) Human excreta must not be used for manure for the period of a year. It must be limed and composted in ditches at least 10 metres from the nearest spring. It can then be used on the land before winter without harmful consequences. (10) Infected persons and suspects must see a doctor. Inoculated persons take the disease in a mild form which resembles influenza. (11) The isolation of infected cases and suspects in hospital is a police order. (12) Disinfection of the patient's room must be carried out immediately after entry into hospital.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended August 21.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

Dr. C. H. Bateman, Medical Officer, Civil Defence First Aid Post Service, Essex, has been commended for brave conduct in Civil Defence.

A meeting will be held at the Charterhouse Rheumatism Clinic, 56, Weymouth Street, W., on Sept. 15, at 5.0 p.m., when there will be discussions on vitamin C in chronic rheumatism, and on an arthritic condition associated with partial scorbutic diet. The meeting is open to any member of the profession.

The National Association for the Prevention of Tuberculosis and Joint Tuberculosis Council has arranged a refresher course in the social side of tuberculosis work for almoners, social workers, and health visitors at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C., on Thursday, Friday, and Saturday, Sept. 23, 24, and 25. The fee for the course is 10s. for three days or 5s. for one day. Early application should be made to Dr. Harley Williams, Tavistock House North, Tavistock Square, London, W.C.

A refresher course in tuberculosis for tuberculosis officers and medical practitioners will be held from Oct. 11 to Oct. 16 (Monday to Saturday inclusive) at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C. This course, under the auspices of the National Association for the Prevention of Tuberculosis and the Joint Tuberculosis Council, is intended to give, in concentrated form, a complete review of the medical and social aspects of the disease. The number attending will be strictly limited to 50, but other courses will be arranged in London and elsewhere at later dates. The fee is 4 guineas for six days or 1 guinea for one day. Early application should be made to Dr. Harley Williams, Tavistock House North, Tavistock Square, W.C.1, from whom the syllabus of lectures and demonstrations can be had.

In the *Journal* of June 5 (p. 711) we published an appeal from a number of distinguished men and women, including the Archbishop of Canterbury, Lord Horder, and Sir Gowland Hopkins, for subscriptions towards the building of a new hospital in Stalingrad. The subscriptions from hospitals all over the country now amount to over £1,000 and, in addition, individual doctors have contributed over £600. But much more is wanted if the hospital is to be a fitting tribute to the Russian defence of Stalingrad. Cheques should be made payable to the Joint Committee for Soviet Aid, crossed "Stalingrad Hospital Fund," and sent to the Organizing Secretary of the Joint Committee, 171, St. Stephen's House, Westminster, London, S.W.1.

The Council of the British Association of Physical Medicine has elected the following officers of the Association for its first year: President and chairman of the Council, Lord Horder; hon. treasurer, Dr. M. B. Ray; hon. medical secretary, Dr. P. Bauwens; hon. general secretary, Sir Frank Fox. Other officers will be appointed when the membership of the Association has been extended. The Council approved 50 new members and consideration of other applicants was held over until its next meeting. Registered medical practitioners interested in physical medicine are invited to apply for membership. The address of the Association is 11, Chandos Street, London, W.1.

In the budget of the London County Council the amount to be voted for hospitals and medical services for 1943-4 is £6,482,735, an increase of £359,350 as compared with 1942-3. The increase is due mainly to cost-of-living additions and increased rates of pay for staff, the bringing into commission of additional beds, an estimated higher average bed occupation, and the continued rise in prices. In addition to the amount mentioned there will be an expenditure of £68,000 in 1943-4 in applying the Rushcliffe Committee's recommendations for increases in nurses' salaries.

During last year 12 institutions were approved by the Central Midwives Board—making 83 in all—for the purpose of giving instruction to midwives in the use of a recognized apparatus for nitrous oxide and air analgesia. The Board has asked the guidance of the Royal College of Obstetricians and Gynaecologists as to the need for persisting in the requirement that when a midwife gives gas-and-air analgesia on her own responsibility to a woman in labour a second person should be present. The reply of the College is to the effect that the presence of a second person is necessary in order to minimize the risk of infection, but the class of second persons allowed to be present is enlarged, and in addition to another midwife, a nurse, or a senior medical student may include a woman over 21 who has been for at least a year a V.A.D. or ordinary member of the British Red Cross Society or Order of St. John or a duly enrolled member of the Civil Nursing Reserve. The Board has also decided to take steps to compile a register of midwives qualified to administer analgesia.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to 1 EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (from 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Attilage Westcent*, London; SECRETARY, *Medisera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Glutamic Acid for Epilepsy

Q.—A patient has sent me a cutting which quotes a report by Drs. Waelisch, Price, and Putnam of the New York Neurological Institute advocating treatment of petit mal by mixed laevo- and dextro-glutamic acid, given in the form of a hydrochloride, in capsules, the dosage being from 12 to 20 g. a day. They report diminution of attacks, together with increased mental and physical alertness. I should like to know whether this treatment has been tried in this country, and if the preparation in question is on the market.

A.—Dr. Tracy Putnam has for many years encouraged investigations into the effect of different therapeutic agents in epilepsy, and work in his department was responsible for the successful applications of the hydantoins, of which epanutin is an example, to the treatment of convulsions. Treatment by glutamic acid is still in the experimental stage, and I have not heard of any controlled trial of it in this country. It should be readily available by special order from any of the large drug firms, but it might be well to delay its use in individual cases until its relative efficiency compared with bromides, phenobarbital, and the hydantoins has been established.

Anatomical Nomenclature

Q.—Immediately after the last war I learned anatomy partly in "New Terminology" (Basle nomenclature) and, especially in the clinical years, also in the "Old Terminology." In reading articles, considering reports about patients and so on, I now find myself very confused. Has any standard terminology yet been agreed upon and universally accepted; and if so, can you recommend a suitable book in this terminology for a G.P. to use in brushing up his anatomy?

A.—A standard English terminology was agreed in 1933 and was accepted by medical schools and publishers. It is a revised form of the "B.N.A." (*Basle Nomina Anatomica*). It was published as a separate report by the Anatomical Society of Great Britain and Ireland, after several years' work by a specially appointed committee, and is sometimes known as the "Birmingham Revision" or "B.R.," since it was finally approved at a meeting of the society in that city. This terminology was introduced into Johnson's *Synopsis of Regional Anatomy* in 1934, Cunningham's *Practical Anatomy* 1935, Buchanan and Cunningham's textbooks 1937, and Gray's *Anatomy* 1938. Most recent editions of anatomy books contain glossaries showing the more important changes from the old contain glossaries showing the more important changes from the "B.N.A." In most foreign countries the "B.N.A." is at present in use, often alongside some indigenous terminology. The "B.N.A." is a terminology agreed by an international committee shortly before the last war. It was intended to replace the various systems in use in different countries, and it gave an opportunity for reducing the number of synonyms which abounded, for example, in the so-called "Old Terminology" in English. It was anticipated that revision would be needed from time to time as new knowledge and experience made it advisable, but this has never been carried out on an international basis. New terms as they arise are frequently linked with some author's name for the sake of clearness in discussion, but it is an agreed policy that personal names should be replaced as soon as possible (as in the "B.N.A."). Confusion of terms in clinical literature arises from the employment by some writers of old names that have been superseded. It is desirable that writers and teachers should conform to the accepted standard terminology.

Adolescent Kyphosis

Q.—A woman patient aged 30 had adolescent osteochondritis, at it is sometimes called. Though it caused no symptoms at the time, she now has three lower dorsal vertebrae semi-fixed, and x-ray examination shows the intervertebral bodies thinned, with some osteophytes on the bodies of the vertebrae. She has pain in the

back, on stooping particularly, but also on walking or standing for more than an hour or so. Massage, sun-ray, and exercise have improved matters, but she wants to get to work, and often the ache prevents her from carrying on with her job. The present attack of pain was due to overwork on her job as cook in a day nursery. What is the prognosis? Any suggestions for treatment would be acceptable.

A.—The condition appears to be what is more commonly described as adolescent kyphosis and is due to the effects of strain, especially lifting or carrying weights, in adolescence, upon a spine weakened by developmental defects or by vertebral epiphysitis. The subject was discussed in the Orthopaedic Section at the Annual Meeting of the B.M.A. at Bournemouth in 1934, and two important papers read then were reported in the *Journal*: the first by Lambriundi (*Journal*, Nov. 3, 1934, p. 800), and the second by Jacques Calvé (*Journal*, Dec. 1, 1934, p. 983). They supply an excellent review of the subject as to both aetiology and treatment. The ideal to be aimed at in treatment is to strengthen the spinal musculature by appropriate active exercises devised to develop a natural muscular "corset." A light spinal brace on the Goldthwait principle may be helpful until the muscles can be developed and trained for the purpose. No treatment is likely to reduce the kyphosis or alter the vertebral condition, but heat and massage, if not overdone, will give relief to the effects of strain. The condition is not likely to get any worse, though the further development of osteophytes—Nature's attempt to buttress the weakened structures—may lead to some lessening of spinal mobility.

Treatment of Syphilis

Q.—Is there any hope of getting a complete cure with injectio bismuthi in a person suffering from secondary syphilitic ulcers? What would be the correct dosage, and frequency, of injections? Is there any preparation of arsenic which can be given either intramuscularly or intravenously which would not cause a reaction? I have a patient who after an intravenous injection of sulpharsphenamine has a severe reaction, with syncope, vomiting, pains in the limbs, etc. What treatment would be the best?

A.—Yes! Injectio bismuthi should at any rate cause the disappearance of the lesions, though it may take a long while to reverse the serum reactions and bring about complete cure. The dosage—assuming the patient is a male of average weight—is 1 to 5 c.cm. (0.2 to 0.3 g. bismuth metal) once weekly given intramuscularly. A careful watch should be kept for gingivitis and also for albuminuria. These injections should be given in courses of 4, with intervals of four to five weeks between courses.

Sulpharsphenamine has very little therapeutic effect on syphilis when given intravenously. It should be given deep subcutaneously or intramuscularly into the buttocks in doses of 0.45 to 0.6 g. once weekly dissolved in 1 to 2 c.cm. of distilled water. These injections are unlikely to cause any general reactions and should be given concurrently with bismuth. The site of all deep subcutaneous and intramuscular injections should be massaged firmly for several minutes after withdrawal of the needle. The two drugs used concurrently should give the best results. If the patient does not prove tolerant, three courses, each consisting of 5 to 6 g. of sulpharsphenamine and 2 to 2.5 g. of bismuth metal, should be given after the blood reactions have been reversed to negative. Intervals between courses may be increased after the first six months of treatment. In view of the fact that sulpharsphenamine occasionally causes purpura it might be worth while trying neosarsphenamine intravenously, but if this is used it would be well to start with very small doses, gradually increasing according to tolerance.

The reactions described are of the nature of nitritoid crises, and may be prevented by the intramuscular injection of adrenaline 0.5 c.cm., 1 in 1,000, a few minutes before the arsenical injection.

Masturbation in Women

Q.—I have recently been consulted several times by women who, in the absence over-seas of their husbands, have developed the habit of masturbation. Although this brings them physical relief, it causes a new strain as they feel they are abnormal. I would be grateful for help in answering the following questions which they put. (1) How widespread is this practice? (2) Can it cause physical harm? (3) Can it make normal intercourse less satisfactory? (4) How can they be helped to overcome the habit?

A.—We have submitted the above question to a woman doctor with wide experience in the sexual problems of women. Her reply follows:

There could be few subjects upon which individual judgment would be more divided than upon this. It seems safe to say that the trend of present opinion is to regard a moderate degree of masturbation as not necessarily abnormal or detrimental. The majority of women may not find unaccustomed celibacy difficult to bear, but many undoubtedly do. Such women find that the condition of continuous sexual tension is liable to be very exhausting and unprofitable and many find that masturbation offers some degree of solution. The cases of masturbation which produce pathological symptoms

are the only ones which usually seek medical advice. They will be found mainly among two groups of people: (1) those who have yielded to the habit in spite of strong conscious or unconscious feelings of guilt; and (2) neurotic patients in whom the symptom is not due to pressure of sexual feeling, but is adopted (as by unhappy children) as a form of pleasure to substitute for feelings of inferiority, or for other deprivations.

Advice given should depend upon the type of case: the former group presents the lesser problem. Many such adults were brought up in nurseries where masturbation was the unforgivable sin. Children were warned that mutilation, sterility, insanity, and even death would result. The horror of such threats is usually "repressed," but their dynamics are responsible for much of the savage condemnation of masturbation, and for the advent of hysterical symptoms (e.g. exhaustion, headache, vertigo, etc.) which are so liable to follow the act in such people. It is necessary to explain these facts and reassure the individual that no physical harm can result. A normally orientated woman will run no risk of coming to prefer masturbation to marital intimacy: this occurs occasionally in people who already have neurotic difficulties which prevent their response to coitus being fully satisfactory. Coupled with such reassurance a reminder is valuable that some reasonable degree of restraint and deprivation may be more advantageous for the personality than over-ready acceptance of comfort. Energies should be directed so far as possible into work, interests, and exercise. Among the second group will be found all degrees of neurotic personality, the semi-frigid and semi-impotent being commonest; here, too, will be the neurasthenics, and often the psychotic types. The treatment of such cases would be too broad a subject for this reply, and the majority of such patients are best referred to the medical psychologist.

Fröhlich's Syndrome

Q.—A boy aged 13 weighs 12 stone, the fat being distributed chiefly about the lower abdomen, buttocks, and thighs. Pubic hair is present but localized, to the region about the symphysis. The testes are partially developed. Is hormone treatment of any value in such a case? The parents are of the working class, and I hesitate to ask them, eager as they are, to spend money on expensive preparations unless there is a reasonable chance of improvement.

A.—This appears to be a partial Fröhlich's syndrome. Testicular development could be augmented or accelerated by gonadotrophic hormone of pregnancy urine, in doses of 500 international units intramuscularly twice a week for six weeks. The adiposity could be mitigated by thyroid and diet.

Combined Diphtheria and Pertussis Prophylaxis

Q.—What in general is the opinion regarding the use of combined diphtheria and pertussis vaccine? Is it safe to use on an infant of 6 months? Would you recommend it?

A.—Combined diphtheria and pertussis vaccine has been shown experimentally to be at least as effective as either antigen used separately.¹ Similarly, combined immunization with tetanus toxoid and T.A.B. vaccine has been shown in the human to be as effective as either preparation alone. It is sometimes stated that infants do not respond well to the injection of any antigen, but Lapin² has recently shown that babies can be immunized against pertussis as effectively as older children. Pertussis is peculiar among the childhood fevers in that it has a considerable incidence among children under a year, estimated at 10 to 20%; even more important, about one-half of the deaths from pertussis occur in this age group. It is therefore advisable to begin immunization against pertussis as early as possible, and it is both safe and wise to immunize any child of six months. Diphtheria, on the other hand, has its greatest incidence later in childhood, and, while immunization may be combined with that against pertussis, it would be desirable to give the child a boosting dose of combined diphtheria and pertussis vaccine one year later.

Beeswax

Q.—What is the chemical composition of beeswax? Have we any ferment which render it soluble and give it food value? If indigestible, has it any action on the bowel causing constipation or diarrhoea if taken in quantity?

A.—Beeswax is a mixture of several substances. Its composition varies according to the method of preparation. The two main constituents are myricyl (melissyl) palmitate ($C_{41}H_{82}O_2$) and cerotic acid ($C_{26}H_{52}O_2$) in the approximate proportions of 6:1. In addition there are small amounts of free melissic acid ($C_{26}H_{52}O_2$), myricyl alcohol ($C_{26}H_{52}O$), ceryl alcohol ($C_{28}H_{56}O$), and two hydrocarbons—heptacosane ($C_{27}H_{54}$) and hentriacontane ($C_{31}H_{62}$). Small amounts of unsaturated fatty acids are also present. Some constants of beeswax are: specific gravity 0.961–0.968; solidification point 60.5–62° C.; iodine value 8.8–10.7; saponification value 88–96; acid value 16.8–20.6; unsaponifiable

well to recently discovered drugs. The incidence of dysentery among enemy troops, on the other hand, has been much higher, and it is said that a part at least of our success at El Alamein was due to the enfeeblement of both Germans and Italians by widespread dysentery.

All honour must be paid to the medical services of the Navy, Army, and Air Force for their successful achievements in maintaining the health and efficiency of the Services under fighting conditions, and credit is also due to the Ministries of Health and of Food and to the medical services of this country for the high standard of health—higher even than it has ever been in peacetime—of the general population. Having paid this tribute, I regard it as a duty to remind you that these health results, both in the Services and among civilians, during war have a more fundamental cause than the administration and practice of medical men. I refer, of course, to the work of those engaged in medical research, who have provided the knowledge for the maintenance of health and the methods for preventing and for curing the deadly diseases of war. So far as I am aware, in the public references made to the subject of health and disease in wartime no credit has been given and no reference has been made to this magnificent achievement of scientific research. The work of Government Departments (Service and civil), of medical men (Service or civil), and of nursing staff in controlling disease can only be as good as knowledge allows it to be, and this knowledge has come, and can only come, by medical research. I suggest that medical scientists have served this country and its fighting Services well, and in counting our blessings let us not forget the enormous debt of gratitude we owe to this small but almost unknown body of men and women, scattered about in the research institutes, universities, and hospitals, who, by devoting their lives to the search for new knowledge, have forged the weapons which have proved so effective for the maintenance and restoration of health in wartime.

The Medical Research Council

In the course of my further remarks it will be necessary for me to refer often to the Medical Research Council, and it may be well to explain what this body is. Although it is an institution of the State, financed by the Government, it is not a large self-contained Department like the Ministry of Health and other Government Departments. The Council itself is a small body which meets once a month, and is made up for the most part of men of great experience in different branches of medical science, changing partially each year. It has a small administrative staff and a larger, though still small, permanent research staff. As its object is to help and co-ordinate medical research generally, much of the work with which it is associated is done in the universities and hospitals of the country, including those of this city, by the professors, lecturers, and medical men on the staffs of these institutions. When, therefore, I talk about the Medical Research Council, this is simply a short way of referring to the organized medical research of most of those engaged professionally in this country in such labours. Any success it attains or has attained can only be regarded as a reflection of our general standard of medical research, and must largely depend also on the maintenance of the good will and active co-operation of these investigators.

Even in peacetime a large proportion of the medical research in Britain is in one way or another associated with the Medical Research Council. In war the natural trend of events makes this association closer. The reason for this is obvious. Most men engaged in research want to direct their energies to the solution of problems that benefit the war effort. A body like the Medical Research Council, working closely with the Services and other Government Departments, is more aware of the immediate problems requiring investigation. In these times, therefore, either research workers ask the Council for advice on important problems or else the Council approaches suitable workers for their help. Working committees are formed of groups of investigators in each subject, so that each worker can be kept informed of the investigations of others and the researches can be co-ordinated. About 40 research committees on different war problems have been formed, and these cover a large part of the field of medical science. Representatives of the Services are members of all war committees. It must

be emphasized that the initiative for action often comes from outside the Medical Research Council.

In peacetime the Medical Research Council does not finance research work which is exclusively of interest to the fighting Services, but from the outbreak of the present war this policy was changed, and all the resources, both of personnel and of finance, were made available for the solution of Service problems. A great reorientation of research took place, fundamental work of a long-term nature being largely replaced by investigations of a short *ad hoc* nature with immediate practical objectives. However, even in wartime, some fundamental research has continued, partly because it is not possible to place every individual worker on a war problem, and partly because some practical problems of war are always arising which can only be solved by a study of the basic principles of medical science.

Under normal peacetime conditions the Medical Research Council has no administrative duties outside the promotion and carrying out of research. On the whole this is a most salutary rule, although it has its drawbacks. For instance, it might happen that great delay in the application of new medical discoveries to the public service would be shortened if the discoverers had some say in administration. On the other hand, if a research department normally undertook administrative duties outside research it would often lead to great friction with the large administrative departments. Nor has it yet proved possible to obtain and retain the best research workers in an administrative department. These men want to work with their own kith and kin in an atmosphere of freedom, and they will not become a subsidiary part of a large administrative machine.

The general attitude of politicians and Government officials to all scientific men is that they must be "on tap" and not "on top"—*vide the Times*. Some scientists say they would not object to this position if there was any evidence that their superior administrators knew when, where, and how to turn on the tap and how to make use of the beverage (not "Beveridge") when they had got it.

If, then, a research department is outside the administrative sphere, it is obvious that it must always be prepared, when asked, to advise other Government Departments on technical matters within its competence, either by supplying information or by making the necessary investigations. As I shall show later, the advisory functions of the Medical Research Council have increased greatly during the war and a number of important actions of Government have been guided by the Council. In addition, even before the outbreak of war the pressure of events forced the Medical Research Council to break its rule and to take on administrative duties, and some of these instances will be mentioned not only because they have been very effective but also because they have filled important gaps in medical service and will probably have to continue in some form or other after the war.

No success could have been obtained had not very close and friendly relations been established in recent years between the Ministry of Health and the Medical Research Council. First let me say a few words about a new service known as the "Emergency Public Health Laboratory Service."

The Emergency Public Health Laboratory Service

The history of the establishment of this service is one of great interest, which will no doubt be told in full some day. It began with discussions between the Medical Research Council and the Committee of Imperial Defence, and more particularly with its secretary, Sir Maurice (now Lord) Hankey, who on this and many other occasions was a tower of strength and a most powerful supporter of scientific projects. The result was that a committee of the Cabinet asked the Council (with the blessing of the Ministry of Health) to organize and prepare for the establishment of this new service, to be ready on the outbreak of war. Laboratories were selected all over the country (mostly in public schools and universities), apparatus was purchased and stored, transport was arranged, and bacteriologists were chosen to take up their duties on receiving instructions. Immediately on the outbreak of war the laboratories were ready, with complete staff and equipment. Fifteen new laboratories were started and 28 other working

laboratories were brought into the scheme, and these are still functioning as one compact service.

It is not possible to disclose all the reasons for this new service, but it will be obvious that one good reason was the expectation that large-scale bombing of industrial centres would necessitate mass movement of the population, and that this, together with the interference with water and other supplies, might well result in epidemics. The fact that there have been no major epidemics during the war and that, indeed, the epidemiological health of the country has been better than in peacetime is at least partially due to this network of laboratories. It has been the constant endeavour of the staff to catch such epidemics at the beginning and, by co-operating with local health authorities, to find and eliminate the cause, and deal with the situation vigorously. By detecting the cause and eliminating it by segregation or otherwise, by determining the methods of spread and dealing with these by inoculation or other means, their efforts have been very successful. Let me give one of many examples of how this service works in dealing with an outbreak of infectious disease.

This is an excellent example of co-ordinated laboratory and field work. The occurrence of several scattered cases of typhoid fever in a certain county was investigated by one of the Emergency Laboratories, and the opinion was formed that the infecting agent had probably been carried by milk. Although most of the patients had been supplied from different dairies, all these dairies had drawn some of their milk from a particular wholesale depot. Inquiry showed that the milk coming into this depot was derived from four different sources. One of these, a group of farms in another county, came especially under suspicion, but inspection of each of the farms failed to reveal the presence of anyone with a history of typhoid fever. The quest for the original source of infection was thus held up for the time being. One point, however, was established: the strains of typhoid bacilli isolated from the patients were referred to a specialist attached to the headquarters of the Service, who found that all these strains belonged to a single bacteriophage type, D4, which had not previously been encountered in Britain. This left little doubt that all the patients had been infected from the same original source.

Months elapsed before a further group of cases occurred, this time in a different part of the county from that in which the first outbreak took place. It was found that the dairy supplying the patients had received milk from the same wholesale depot as before, and again the organisms isolated from the cases belonged to the D4 type. The clue to the puzzle was provided later, when a single case of typhoid fever occurred in the other county from which some of the depot's milk supply came. Inquiry into the source of infection in this case showed that the patient had until recently been employed as a milkman at one of the farms of the group that had been under suspicion a year earlier. A full investigation at this farm led to the discovery that the owner, although his medical history had not given rise to suspicion on the former occasion, was in fact a chronic typhoid carrier. It could therefore be concluded that, through faulty personal hygiene, he had occasionally infected the milk which he had been sending to the wholesale depot. Thus the co-operation of several laboratories with each other and with field investigators led finally to the detection of the distant source responsible for the outbreaks.

Blood Transfusion Service

The prime movers in the promotion of the Blood Transfusion Service, now so active and successful throughout the country, were a group of pathologists who independently came to the Council a year before the outbreak of war (indeed, immediately after the Munich episode) because they needed some official backing and a central organization to carry out their ideas.

The Council limited its own activities to the establishment and running of the four London blood transfusion depots, to the erection of plasma freeze-drying plant, and to helping the Navy, Army, Air Force, and Emergency Medical Service in their own efforts to supply blood or its products for transfusion, either by advice or investigation or by providing additional supplies. The spin-freeze-drying plant, for which the Wellcome Foundation supplied £20,000, is a fine example of ingenuity and skill. It is capable of drying 5,000 bottles of plasma a week (each bottle containing the blood plasma of three donors). It actually dries 2,500 bottles a week, and of these 800 bottles are for the Navy, 800 for the Army, and the remainder are distributed according to demand (Navy, Army, Air Force, and civilian). In addition the staff of this

service have carried out a great deal of research on blood compatibility and incompatibility, and have certainly improved the quality of the transfusion products. There has been a fine spirit of co-operation among all workers, both civil and Service, in this important project, and the country owes a debt of gratitude to them for providing both the civil population and the Forces with the vast amounts of material for transfusion that have been forthcoming. The lives of thousands of wounded Service men and civilians have been saved by transfusion in this war, and it is to be hoped that an organization of a similar nature, to cover the needs of the whole country, will remain in peacetime.

Pooling and Dispersal of Biological Immunizing Products

On behalf and at the request of the Government, the Medical Research Council made arrangements before the war for the pooling and distribution of emergency immunological agents to meet the partial needs of the fighting Services and the anticipated requirements of the civil population. By undertaking the provision of large stocks of such agents as tetanus antitoxin, gas-gangrene antitoxin, diphtheria toxoid, and various vaccines such as typhoid-paratyphoid, typhus vaccines, and other sera and acting as a central distributing agency, it is obvious that much expense was saved to the country, properly controlled distribution was obtained, a strict eye was kept on the potency and general excellence of the products, and new discoveries of importance were quickly brought into use in their preparation.

Registration and Allocation of Pathologists

In addition to these services the Medical Research Council set up a committee in 1938 to keep a register of and to allocate pathologists to war emergency duties. This committee has filled a most important gap in the medical services, and its very success in arranging for the supply of competent pathologists to the civil and military hospitals, both here and abroad, and also for that of laboratory assistants at a time when there is but a limited supply of such people, has hidden the difficulties of the task and even its very existence.

Advisory Functions of the M.R.C. in War

It may be well now to refer briefly to some of the more important instances in which organized medical research has been called on during the war to give advice to various Government Departments. Sometimes this advice could be given immediately on the basis of present knowledge, but often a considerable amount of *ad hoc* research had to be carried out to obtain the necessary information.

Food and Nutrition

Research workers on nutrition have had the satisfaction of seeing the adoption during wartime of some of the teachings on nutrition that they have been urging during the past 20 years or more. Among those worthy of mention are the increased consumption of milk by infants and children and by pregnant and nursing mothers also the increased consumption of potatoes and other vegetables and the change of bread made from white flour to flour of higher extraction. It would, however, be idle to think that all these changes took place because it was thought that they would be nutritionally advantageous. This was probably the reason in the case of milk but the economic and supply factors were the paramount causes in the bread and vegetable changes. It is, however, no good quibbling over the reasons; the fact is, the changes have been made and the country's health has improved accordingly.

The Medical Research Council took a strong line over the bread question almost from the beginning of the war, and published memoranda on the need for adopting an 85% extracted flour with a minimum of fibre and a maximum of wheat germ, vitamin E complex, and iron, together with additional calcium carbonate. With the excellent co-operation of the workers in the Cereals Division of the Ministry of Food, test loaves were made and detailed specifications of the desirable bread were issued. These were ultimately adopted by the Ministry, except that they halved the proposed amount of calcium carbonate. This was a pity, because the basis of this advice was most carefully considered and the proposals were unanimously made, both by scientists and by clinicians consulted by the Council. Some further improvement in the calcium content of bread has been recently made by the addition of 2 lb. of dried separated milk to 250 lb. of flour. The need for adding vitamins A and D to all margarine was also strongly pressed.

One of the paramount difficulties of mass feeding under conditions of control and restriction has been to find the best means of dealing with exceptions, such as are presented by invalids and those requiring special food. Action in this respect has been taken by the Ministries of Food and of Health on the advice of a special committee set up by the Medical Research Council known as the Food Rationing (Special Diets) Advisory Committee. Besides meeting the nutritional needs of those really requiring special consideration, this committee has to deal with people—only a small proportion of the whole, but a large number *in toto*—who think they are ill or who are full of special fads and fancies. All kinds of diseases have been catered for—diabetes, tuberculosis, steatorrhoea, dyspepsia, fevers and other acute illnesses—and the consensus of opinion is that the scheme has worked well. All individual cases, on special grounds, were considered by members of the committee and received careful attention. Any criticism there has been is largely due to misunderstanding of the problem to be faced. The view of the committee is that special feeding arrangements, in time of restriction, can only be made which aim at the rapid return of sick people to work or the retention at work of those chronically ill. It would be easy and natural to be kind to all sick and old people and give them the best of everything, but what they got in this way would clearly be at the expense of healthy people who have to carry on the work of the country and who must be kept healthy. Decisions were therefore made strictly on medical and scientific grounds with these objects in view, and compassionate grounds were not allowed to influence their advice. With very few exceptions, the medical men of the country have played their part well under difficult circumstances. Taking into account the great difficulties met with in rationing in the last war because of the claims of invalids, it cannot be considered that the labours of this committee have been in vain.

Drugs

On the whole the country has been well served with supplies of essential drugs. In the last war the Medical Research Council learned its lesson in the case of arsphenamine (salvarsan), an essential substance for the treatment of syphilis discovered by Ehrlich and supplied to us entirely by Germany. There were hardly any stocks in this country at the outbreak of the last war, and since none could be imported it fell to the Medical Research Committee (now Council) to arrange both for the study of its preparation and for large-scale manufacture. The inexplicable toxicity of some batches of the drug greatly added to the difficulty of supply. Even to this day all new batches of arsphenamine and its products are tested biologically before sale. Well before the present war, with the approval of the Committee of Imperial Defence, the Council initiated a movement which ensured that all essential foreign drugs not previously made in this country should be manufactured here if war broke out. A list of these drugs was drawn up and the Association of British Chemical Manufacturers was invited to divide the task of studying their preparation and manufacture among different firms, and so the position was secured. Except in the case of mepacrine (the German atabrin), the needs of which suddenly became enormous because of the loss of the world's main source of quinine when Japan took the Dutch East Indies, these arrangements have worked satisfactorily and, so far as supplies are concerned, no sick person has gone without the proper treatment for his condition.

As regards drugs in general, the Therapeutic Requirements Committee of the Medical Research Council has advised the Ministries of Health and of Supply on allocations when shortages of drugs were apparent, and have suggested substitutes. They also classified all drugs in categories of relative importance, so that these Ministries knew beforehand how essential each substance was in treatment and how urgent or otherwise it was that imports should be maintained or increased.

It would be possible to spend much time on this question of advice given by the Medical Research Council during war, but I must limit myself to the brief mention of two other instances. The Care of Shipwrecked Personnel Committee has advised the Navy and Ministry of War Transport on the care of shipwrecked sailors. Much research had to be carried out on the many problems raised. Most of these experiments had to be made on human beings, and it may be of interest to add that for part of this work conscientious objectors volunteered their services and cheerfully suffered a good deal of discomfort. One notable decision was made by this committee—namely, that water supplies were far more important than food supplies to shipwrecked sailors—and action was taken accordingly.

When the incidence of tuberculosis greatly increased early in the war, the Ministry of Health asked the Council to study this subject, giving its members the widest terms of reference. The committee set up to do this work not only designed a new mass-radiography apparatus, which will shortly be in general

use, and tested it on thousands of workmen and others, but also drew up a scheme for the care and treatment of tuberculous people, which was accepted by the Government and formed the basis for legislation. This was no mean achievement, and will have great repercussions on the incidence of this disease in the near future.

I have given an account of these co-operative developments of wartime because they seem to me to illustrate how a research body and administrative Government Departments should work together, and how fruitful and rapid such co-operation can be. If only this system could be continued and extended we should hear much less about the frustration of science.

Nevertheless, I should be sorry if I gave the impression that all liaison work of this nature has been as successful as the instances described. Much has been said and written during the war about the failure of Government Departments to make use of scientific help. Great improvement seems to have taken place in this respect, especially in the physical, chemical, and engineering sciences, but there are still many sad failures and delays to bring the fruits of medical science into the war effort. These are generally due to human frailties and not to wrong machinery.

Medical Research for the Fighting Services

Much of the research work previously mentioned has been concerned primarily with civil life under war conditions and only secondarily with the Services. I should like to refer briefly now to war work with greater implications to the Services and less, but still often substantial, advantage for the civil population. This has fallen into two main groups: first, work of a clinical and pathological nature on such problems as wounds, burns, fractures, infection of damaged tissues, traumatic shock, blood transfusion, and brain and nerve injuries; secondly, the study of the best means of increasing the efficiency, safety, and comfort of fighting personnel. This latter group calls for investigation mainly by physiologists and psychologists.

As regards the work centring round wounds and injuries, the two main problems are those of traumatic shock and infection, which are the factors determining death. If shock and infection can be avoided or treated satisfactorily, modern surgery can ensure recovery after the severest mutilation. Briefly, the research work on traumatic shock has been disappointing in spite of the greatest efforts both here and in America, and no doubt also in enemy countries. Between the two wars practically no advance in fundamental knowledge of the subject took place and nothing comparable to the discovery of blood transfusion that came in the last war. Methods of transfusion of blood and its products have, of course, improved, and their use has been greatly extended, but we have little or no more knowledge of the pathological process of shock, and there are still many instances of shock developing and proving fatal in spite of blood transfusion. Confusion has been introduced into the study of shock by the difficulty of defining the condition, and some research workers have been more iconoclastic than constructive in their teachings. Histamine as the curative agent, accepted in the last war, has been generally repudiated. The histamine hypothesis served its purpose well, for it was mainly instrumental in introducing the practice of treating shock by blood transfusion. A small beam of light on the subject of traumatic shock has recently appeared from a neighbouring university, but whether it will wax or wane in strength only the future can tell.

In the case of infection, both general and wound infection, quite another story must be told; it represents the greatest medical advance of the war, and will be of inestimable value to mankind at all times.

A Great Medical Advance

The astounding advance in recent years in combating generalized blood infection by chemotherapeutic drugs is so well known as to require but little emphasis. Deadly diseases like streptococcal septicaemias, cerebrospinal fever, and pneumonias have had their lethal effects greatly reduced by the sulphonamide derivatives. Great progress has been made on this subject, even during the war, and newer and better sulphonamide drugs, which are both more effective in their action

and less toxic to the patient, have been discovered. Their field of action is also being extended, and now includes excellent curative effects of the more insoluble products, sulphaguanidine and succinyl sulphathiazole, in bacillary dysenteries and probably even in the diarrhoeas of infants and young children, which account for so many deaths in this country.

Recent reports from Britain and from the U.S.A. all bear witness to the remarkable curative effects of penicillin. The great difficulties of making this substance on a large scale are gradually being overcome, but it will probably be some time before it is an easily acquirable remedy. Penicillin has important effects even in staphylococcal septicaemia, a condition which previously has not responded to treatment even with the sulphonamide drugs. In a large series of such cases in the U.S.A. treated by penicillin, previously nearly always fatal, the mortality rate came down to 20%. In chronic bone infections also, which have previously resisted all treatment for months or years, the curative effect of penicillin has proved to be very great. Penicillin has the advantage of curing infections by many sulphonamide-resisting micro-organisms. Almost every week new fields in which penicillin is effective come to light.

So far I have mentioned the use of these bacteriostatic drugs given systemically, but mention must also be made of a very important development of the war—namely, the successful local treatment of infected wounds and injuries. Many will remember that the vast experience of the last war indicated that treatment of wounds by antiseptics was regarded generally as a failure. Medical research in this war is coming to the opposite conclusion, and we are now, by the use of these substances, in the position of having much greater control of wound sepsis. The same applies to burns and industrial injuries. Lister would have been interested in this turn of the wheel.

The recent success of local treatment depends on the discovery of new antiseptics—the sulphonamides, especially sulphamamide and sulphathiazole; also penicillin, propamidine, and the amino-acridine compounds, of which proflavine (2:8-diamino-acridine) is the best-known. Almost as important in the success attained in this field is better knowledge of how to use antiseptics.

It is interesting to note that, except for the sulphonamides and in this case, also, their early clinical establishment depended largely on British research, the development of these drugs and the knowledge of their antiseptic properties in wounds has been mainly done in this country. Much of the success obtained in this recent work has depended on discoveries related to the right way of applying them, and this side of the problem still needs extending. What is required is low solubility, which allows a small but effective concentration, together with long persistent action. These conditions have been obtained with the sulphonamides, proflavine, and propamidine, which are applied to the wounds in solid or semi-solid form and allowed to act over long periods. Penicillin, while very strongly bacteriostatic, has the drawback of being too rapidly absorbed and requires constant application, but recent work indicates that it may be possible in the future to use preparations which, while themselves inactive, slowly dissociate, with the liberation of active penicillin.

Generally speaking, the advance in the treatment of infection by systemic, alimentary, and local methods has been amazing, and it looks as if, apart from virus infection, the back of this important problem is broken. The value of recent medical research in this field, both to man and to animal, cannot be exaggerated, and a victory over disease has been won which, in terms of saving life, will in a short time far surpass the losses caused even by such events as world wars.

Nothing can be more important than that the medical man, both Service and civilian, should realize his responsibility in keeping abreast of this rapid development in treating infection, both local and generalized, by these drugs. It is unpleasant to be constantly reminded that gonorrhoea is on the increase in this country, at a time when doctors have at their disposal a drug which, some experts declare, will cure 90% of such cases in three days' treatment. It is of interest to note that sulphonamide-resistant gonorrhoea cases, which, although relatively few in number, are a real social burden, can be cured in two days by penicillin.

Research on Fighting Personnel

One of the most remarkable developments of the war, which has been largely in the hands of medical scientists, has had nothing to do with the study of clinical conditions, but has been concerned with the maintenance of the safety, efficiency, and comfort of fighting personnel. With the vast mechanization of combat the tendency has been to centre most interest on instruments of war and to leave the men who had to use such instruments to get on as well as they could. Many machines were not only intricate in their nature but placed the individuals working them in such unnatural conditions that it was impossible to retain their efficiency and often, indeed, their judgment or consciousness. Many instruments of war demand the highest skill and intelligence. An aircraft, a tank, or a submarine with crews whose surroundings have lowered or deprived them of this intelligence is not much use. Again, all such instruments must be so designed as to allow the men to work them in comfort. Personnel must also be chosen who have the best natural aptitude for working them. The growing importance of these and many related problems has resulted in the setting up of three committees—the Flying Personnel Research Committee, the Military Personnel Research Committee, and the Royal Naval Personnel Research Committee. The first of these was started by the Air Ministry a year before the outbreak of war, and the Military Personnel Research Committee and the Royal Naval Personnel Research Committee are committees of the Medical Research Council, upon which the Army and Navy respectively are strongly represented, appointed during the war. Each main committee has a number of working subcommittees to investigate special problems. While it would be wrong to give the impression that this line of research is entirely novel, it is true to say that the war has tended to emphasize its importance and to crystallize the point of view of the primary need for looking after the interests of the fighting man in relation to his weapon and his environment. Both lack of time and the necessity for war secrecy prevent me from dealing with this particular aspect of war research in any detail, but probably I can best give you an idea of the work and the kind of problems to be studied by referring briefly to some of the abnormal conditions an air crew have to withstand and yet retain the fullest intelligence. As an aircraft ascends the atmosphere becomes rarified and the pressure of oxygen diminishes. Ascending from sea level, aviators breathing ordinarily would become unconscious at an altitude of 16,000 feet, and they therefore require oxygen supplied to them from cylinders and delivered to their lungs through masks well before this height is reached. Even breathing pure oxygen in this way, they would become unconscious at about 42,000 feet, and above this height must breathe it under pressure, and, since the lungs would refuse to work if the pressure were applied only through their mouths, it is necessary that the oxygen should be supplied under more complicated conditions. But oxygen is not given simply to retain consciousness in the airmen. Consciousness may well be retained, but the crew may lose their intelligence and judgment. An individual who is only partially supplied with oxygen is rather like a drunken man, and not only does not realize his incompetency but also resents being told this fact. Such a mental condition can have almost unbelievable effects on behaviour, and you may have heard stories from time to time of such incidents. One such case was related recently by Dr. Bryan Matthews, who is head of the Physiology Laboratory of the Royal Air Force. While at a great height the pilot announced to the crew through the intercommunication set that he was about to land. He thereupon guided his plane gently along the upper surface of a cloud. Descending rapidly through the cloud he then proceeded to tell the crew to get out and began to do so himself. Fortunately the navigator understood what was happening and rapidly seized the controls. There is no place for amusing episodes of this kind in an aircraft, and not only is the efficient supply of oxygen a matter of first-class importance in aviation but the varied conditions to be met make it a difficult problem to ensure this.

In addition to the provision of oxygen supplies for aviators, there are a number of other important conditions from which they have to be protected. When an aircraft turns in the air the crew and plane itself are subjected to an increase in

gravitational effect. This may be 3, 4, 5, 6, or more times ordinary gravity, according to the speed of the aircraft and curvature of the turn. At about 5 g. blood is driven from his retina and he develops the condition of "black-out"—i.e., he is momentarily blind. At about 6 g. he becomes unconscious, again only temporarily, but during these few seconds he may have covered much space and, since he may be turning to avoid action or chasing an enemy plane, it is of the greatest importance that his wits and eyesight should be perfect during the turn. The problem therefore is to provide the airman with such conditions that his threshold for blacking-out is high, and yet it must not be higher than that which the aircraft will stand. Full consciousness would be no consolation if the aircraft broke up. Another trouble aviators have to meet at high altitude is due to the nitrogen dissolved in their blood coming out of solution and forming bubbles. These cause intense pain in joints and muscles, which may pass on to collapse and unconsciousness; and the condition is known as "bends." It is now known that "bends" can be mitigated by washing out the nitrogen from the tissues before ascent.

You will see that these problems require much research, and it is the object of the physiologist to arrange his investigations so that as performance of aircraft becomes greater so also must the airman be kept provided with better means to increase his own powers of control. So far the physiologist has responded to all calls, and improvement in aircraft performance has been accompanied by equal powers of control. Submarines and tanks also have their own problems, and much work has been done to promote the efficiency of their crews under the many different conditions which may arise. It would be possible to give many other examples of investigations on personnel necessary in wartime—clothing to meet the extremes of heat and cold as met with in Persia or on an Arctic convoy respectively, the best diet for normal and extreme conditions, food for special purposes like commando operations, conditions for optimum vision in the dark. Probably I have said enough to show that this kind of research on fighting personnel is of very great importance.

Conclusion

I have now given a general survey of medical research activities during the war. I regret that, for obvious reasons, I have not been able to include in it an account of many of the more interesting discoveries that have been made, but most of these will come to light in course of time. The advance of medical science, both before and during the war, has been fantastic.

This lectureship has been instituted in memory of a man whose outstanding quality was to apply scientific knowledge to the service of man. The work I have attempted to describe is exactly of this nature, and I am sure it would meet with his approval when I express the wish that this lecture be regarded as a tribute to all those engaged on medical research in this country. Sitting as I do at the centre of all these activities I am in a position to say that this body of men and women—pathologists, bacteriologists, physiologists, biochemists, pharmacologists, and clinicians—deserve well of their country for the unsurpassed quality of their work, for their devotion to its performance, and for their complete unselfishness in carrying out their allotted tasks.

The American Society for Research in Psychosomatic Problems held its first annual meeting on May 9 to 11, when a constitution was unanimously adopted and the following ten research committees appointed: on psychosomatic problems in obstetrics and gynaecology, in early infancy and childhood, in physiological mechanisms, in war medicine, in internal medicine, and in industrial medicine; psychosomatic implications of animal experimentation; psychosomatic teaching in medical schools; psycho-analytical research in somatic problems; and the psychosomatic approach to social psychosomatic problems; and the committees will correlate and initiate and cultural problems. These committees will present an annual psychosomatic research in their different fields, present an annual report, and suggest programmes for meetings of the Society and societies. The papers read to a joint meeting of the Society and the American Psychiatric Association on May 15 discussed new methods of psychosomatic diagnosis, including new Rorschach techniques and a new electronic method for measuring and recording deviations in psychosomatic functions.

PITUITARY HYPOTHYROIDISM WITH IMPAIRED RENAL FUNCTION

BY

G. E. BEAUMONT, D.M., F.R.C.P.

Physician to the Middlesex Hospital

AND

J. D. ROBERTSON, M.D., D.Sc., D.P.H.

Clinical Chemical Pathologist, Middlesex Hospital

(From the wards and Courtauld Institute of Biochemistry, Middlesex Hospital)

The following case presented certain features suggestive of hypothyroidism and nephritis. A series of investigations confirmed the diagnosis of a clinical syndrome related to a disorder of the pituitary gland which may be called pituitary hypothyroidism. This appears to be a rare condition, and resembles in many respects the few cases of pituitary myxoedema which have been reported.

Case Report

The patient is a female, single, aged 26. The present illness began at the age of 19, and there is little of significance in the history previous to this. The signs and symptoms in order of their appearance were as follows:

Abdominal Discomfort.—This was her first symptom; and she described it as a "fullness" even after small meals (aged 19). She also had acute attacks of diarrhoea.

Thirst.—Two years later (aged 21) she had severe attacks of thirst, especially in the winter. They were periodic, and are still present.

Oliguria.—She noticed that the output of urine fell appreciably with the onset of the thirst. At times micturition was very painful.

Swelling of Legs and Face.—At the age of 23, in the winter, she complained of periodic swelling of the ankles and legs. The leg muscles would become hard "like wood," making walking very difficult. The face and wrists also swelled periodically.

Cramps and Tetany.—She complained of slight cramps in the hands and legs at the age of 25. These became so severe that a tetanic attack in the hand often followed the taking of her blood pressure.

Coma.—A few months after the onset of tetany she became very weak and drowsy, with oliguria leading almost to anuria, bradycardia, marked fullness in the abdomen, and constipation. The attack lasted about 7 days. Two months later she had another and more severe attack during which she slept for three days. She appeared to make gradual recovery from both attacks.

Throughout the course of her illness this patient was admitted to various hospitals for investigation on four occasions. Only on the last occasion was a diagnosis made and treatment instituted. She was considered to be a case of "latent nephritis" because of a diminished urea clearance (an average of 25% of normal) and a urinary protein of 0.08%. She was advised to restrict her fluid intake, avoid salt, and be sparing with protein.

She was first seen by one of us (G. E. B.) on April 10, 1941 or one month after her most recent discharge from hospital. She was then aged 26, her height 5 ft. 3 in., and her weight 84 lb (i.e., she had lost 17 lb. since the beginning of her illness). She was thin but not emaciated, and neither her mental nor her physical condition suggested anorexia nervosa or myxoedema. Her skin had been very dry, with absence of perspiration, since the age of 16. The pubic hair was of female distribution; eyebrows, axillary hair, and hair on head were normal. She had noticed more hair on the arms and legs during the last four years, and on the thighs and upper arms during the last few months. Her appetite was good. The heart was normal, the blood pressure 110/60, the arteries not thickened, and pulse 60. Micturition occurred on an average only twice a day, and the output was scanty. Her menstrual periods began at the age of 14, and were regular until she was 16. There were no periods from 16 to 17, when they recurred and were almost regular until Feb., 1942 (aged 25). She then missed one period, and had no more after May, 1942, until they returned in Jan., 1943, when she was under treatment. They have since been regular. There appeared to be little else abnormal on physical examination.

It seemed improbable that she was suffering from nephritis of such a severe type as to lower the renal function to 25% (van Slyke), when the urine showed no casts and only an occasional trace of albumin, and there was no other clinical evidence of

nephritis. The periodical swelling of the malar regions of the face and the hardening "like wood" of the leg muscles from time to time suggested the possibility of masked hypothyroidism, a condition to which attention has been drawn by Beaumont and Robertson (1939). Dodds and Robertson (1939), and Beaumont (1941). Unexplained diarrhoea is also sometimes due to this cause. The basal metabolic rate was determined, and was -21 (Aub-DuBois), and the blood cholesterol was 170 mg. per 100 c.cm. It now occurred to us that the low van Slyke reading might be due to hypothyroidism rather than to a primary affection of the kidneys. It is known that in primary myxoedema a diuretic crisis usually occurs as soon as the patient responds to thyroid administration. This suggests that renal function is impaired in myxoedema, at any rate so far as water elimination is concerned. The normal blood cholesterol figure suggested that the hypothyroidism was not primary, for in primary myxoedema the blood cholesterol is almost always raised in untreated cases.

Progress.—As she was not now considered to be suffering from nephritis she was put on a normal diet with as much salt and water as she desired, and thyroid medication was begun with gradually increasing doses, from $1/4$ gr. to 3 gr. daily. At first her condition greatly improved until she had taken 3 gr. a day for a month. She then complained of feeling very ill, with intense lassitude, dizziness, retching, diarrhoea, and acute abdominal discomfort. The pulse was 100 , and the temperature 99° to 100° F. The urine output fell to 35 oz. a day. She looked very ill, was dehydrated, and had sunken eyes, a sallow greyish complexion, and dry skin. She was admitted to hospital for further investigation. Her blood chemistry gave the following findings: urea 87 mg., plasma chlorides 450 mg., serum sodium 291 mg. per 100 c.cm. In other words the urea had risen, the chlorides and sodium had fallen—a condition typical of an impending adrenocortical crisis. The urea clearance had fallen to 13% of normal. It is known that the administration of thyroid causes acute adrenocortical failure in cases of Addison's disease and in pituitary myxoedema.

The diagnosis of simple hypothyroidism was now considered as only part of the syndrome, the condition being probably a multi-glandular deficiency with the primary lesion in the pituitary gland. When her condition had improved further tests were carried out. A radiograph of the pituitary fossa was normal, and there was no evidence of a suprarenal or renal tumour as judged by clinical abdominal examination, a direct radiograph of the abdomen, and the uroselectan test. An "insulin-tolerance curve" was carried out on the standard lines described by Himsworth (1935), Fraser, Albright, and Smith (1941), and Fraser and Smith (1941).

Blood Sugars after Intravenous Insulin (the Resting Sugar taken at 100 mg. per 100 c.cm.)

	Resting	After 5-6 Units of Insulin Intravenously						
		20 min.	30 min.	45 min.	60 min.	90 min.	120 min.	
Normal	100	45	50	70	80	95	115	
Our case .. .	100	55	55	60	60	85	80*	
Case of pituitary hypofunction*	100	55	40	40	45	75	60	

* Lerman and Stebbins.

Our case showed "hypoglycaemia unresponsiveness" and failure of the diabetogenic hormone typical of hypofunction of the pituitary gland. In other words, there is a 50% fall in the blood-sugar level in 20 or 30 minutes, and at the end of two hours the blood sugar is less than 90% of the fasting level.

Urinary System.—A series of tests was carried out on the renal function. The urea clearance was repeated, and was found to be 19% of normal. In addition there was impairment of water elimination—only 350 c.cm. of urine were excreted three hours after ingesting a litre of water—and inability to concentrate urine above a specific gravity of 1011 . Despite these signs of renal impairment the blood urea was now normal (33 mg. per 100 c.cm.), the urine contained no albumin, and no abnormalities were found microscopically in the centrifugized urinary deposit. There was no previous history of nephritis, and the blood pressure was normal.

The diagnosis of pituitary hypofunction now appeared to be established. Such a syndrome would explain a combination of a multi-glandular deficiency affecting the thyroid, adrenal, and sex glands, giving hypothyroidism, cortico-adrenal insufficiency (accentuated by thyroid therapy), and amenorrhoea. The effects of replacement therapy were then studied.

Treatment and Progress.—The treatment included sodium chloride, cortical extract of suprarenal glands (later desoxycorticosterone acetate), pregnant mares' serum, and thyroid. Sodium chloride was given by mouth in doses of 180 gr. daily. Suprarenal extract (eucortone, Allen and Hanburys) was given daily intramuscularly in doses first of 2 c.cm., increasing by 2 c.cm. every second day up to 10 c.cm. After a month this was replaced by desoxycortico-

sterone acetate (percorten, Ciba) 5 mg. intramuscularly on alternate days for 14 days. Pregnant mares' serum (gonadyl, Roussel Lab.) was given daily intramuscularly in doses of 400 mouse units for two months, and thereafter three times a week for six months: now it is being given three times a week for two weeks every month before her periods are due. Thyroid was stopped for a month in view of its effect on the adrenocortical deficiency, and now is being given in doses of $1/2$ gr. twice daily.

The patient made considerable improvement as soon as the above treatment was instituted. She felt more energetic and looked well. Menstruation restarted. After six weeks of treatment her urea clearance rose to 44% of normal, and five months later it was within normal limits, with a greatly improved water elimination. Her weight has increased by over 16 lb., and she is now (June, 1943) back at work, her periods are regular, and she is feeling very much better in every way.

Discussion

In 1914 Simmons described a syndrome which manifested itself clinically in a pronounced loss of weight, premature senility, diminished sexual functions, weakness, and loss of hair. The finding at necropsy was almost complete destruction of the anterior lobe of the pituitary gland. The clinical symptoms closely resembled anorexia nervosa, and the differentiation between these diseases was difficult. Cachexia is not now considered a characteristic feature of Simmons's disease. More recently some unusual types of a pituitary syndrome have been described. Thus Castleman and Hertz (1939) reported a case of pituitary fibrosis with myxoedema. The case looked, and was, myxoedematous, with a blood cholesterol of 374 mg. per 100 c.cm. Although not suggested by the authors, it seems probable that the Simmons's disease developed in an established case of myxoedema. The parathyroids were fatty, the adrenals and ovaries atrophic, and the anterior lobe of the pituitary and the thyroid showed fibrosis. Lerman and Stebbins (1942) have reported two cases of the pituitary type of myxoedema, with typical myxoedema and the pituitary syndrome, including hypogonadism, adrenocortical insufficiency, and decreased diabetogenic activity. In one case in which it was estimated, the cholesterol was 120 mg. per 100 c.cm.—an unusual finding in primary myxoedema.

Our case possessed the following features typical of Simmons's disease: hypogonadism, adrenocortical insufficiency, and a decreased diabetogenic activity, together with hypothyroidism. The patient did not look myxoedematous and the blood cholesterol was normal, which suggests that the hypothyroidism was not primary. The only signs of a masked hypothyroidism were the "wood-like" stiffness of the leg and arm muscles and the dry skin. The most prominent sign in our case (and not previously referred to in the literature) was evidence of renal impairment as shown by diminished urea clearance, diminished water elimination, and a urine of low specific gravity. In a further paper it will be shown that only part, and not all, of these renal signs could be due to the hypothyroidic factor. In view of the improvement of the urea clearance and in the water elimination after treatment with the various forms of therapy (thyroid, adrenocortical, and gonadal hormones) it seems probable that the renal signs were in fact a manifestation of the disease.

Summary

A case of pituitary hypothyroidism is described which presented the following signs and symptoms. (1) Renal impairment:—This was the most prominent sign, and at first suggested a diagnosis of "latent nephritis." The urea clearance and water elimination were diminished, and there was a urine of low specific gravity. (2) Hypothyroidism:—This is to be distinguished from the typical primary myxoedema, in which the blood cholesterol is usually raised. (3) Cachexia. (4) Adrenocortical insufficiency. (5) Hypogonadism. (6) Decreased diabetogenic activity.

Treatment with sodium chloride and the hormones of the thyroid, gonads, and adrenal brought about a marked improvement in the clinical condition and restored the renal function to normal.

HUMAN INFECTION WITH BACT.
CHOLERAEE-SUIS

A REPORT OF TWO CASES

BY

HERTA SCHWABACHER, M.R.C.S., L.R.C.P.
Central Laboratory, Sector IV, E.M.S.JOAN TAYLOR, B.Sc., M.B., B.S., D.P.H.
Emergency Public Health Laboratory, Oxford

AND

M. H. GLEESON WHITE, M.B., B.S.
Central Laboratory, Sector V, E.M.S.

First isolated by Salmon and Smith in 1885 from pigs suffering from swine fever, and subsequently reported from various parts of the world as a cause of epidemics of acute food-poisoning, *Bact. cholerae-suis*, and the *kunzendorf* variant described by Hirschfeld (1919) and MacAdam (1919), have from time to time given rise to sporadic cases of generalized infection in man. Harvey (1937) published a detailed report of 21 such cases admitted to the Johns Hopkins Hospital over a period of four years. In a wide review of the literature he was able to find only 50 other proved cases, as opposed to 1,425 of the acute food-poisoning type. Since then Ravitch and Washington (1937), Cole and Nalls (1938), Clifton and Werner (1938), Hardison and Shipley (1941), Henderson (1942), and Neter (1942) have contributed individual cases, and Goulder, Kingsland, and Janeway (1942) in a more comprehensive paper have added a further 11 cases of their own.

Although in this country 12 (3.6%) of the 331 *Salmonella* food-poisoning outbreaks studied by Scott (Reports, 1923-38) were attributed to these organisms, only 4 examples of the generalized type of infection appear to have been recorded: two by Nabarro, Bruce White, Dyke, and Scott (1929), and one each by Boycott and McNee (1936) and Guthrie (1941). It would therefore seem worth while reporting the following two recent cases.

Case I (H.S.)

A woman aged 40 was admitted to Shroddell's Hospital under the care of Dr. M. E. Roberts on April 23, 1942, with pyrexia. She had been delirious on the night before admission. There was no history of abdominal discomfort, or of gastro-intestinal disturbance in any member of the patient's household.

On admission she was lethargic, stuporous, and obviously very ill. Her general condition suggested septicaemia; temperature 102° F., pulse 140, respirations 40. There were a few small clean healing areas on her right hand, said to have been the result of chilblains. The heart sounds were poor in quality, but no murmurs were audible. Blood pressure 110/80. No abnormality was detected in the central nervous system. The abdomen was not distended or tender, and the spleen was not palpable. There was no rash. A radiograph of the chest showed that the heart was atonic and somewhat dilated, and that the lungs were hyperaemic. A blood culture was taken on admission, and while awaiting the result she was treated expectantly with sulphapyridine, pentnucleotide, and cardiac stimulants. As a result of enemata she had two normally formed stools. Her condition deteriorated steadily, and she died on the sixth day of the disease.

Laboratory Findings.—The blood culture taken into liquid broth on admission (second day) was incubated aerobically, anaerobically, in 10% CO_2 in air, and yielded an organism of the *Salmonella* group. A blood count on the same day showed W.B.C. 7,600—lymphophonuclears 90%, lymphocytes 8%, hyalines 2%. There was a "shift to the left" without an absolute leucocytosis. The bacteria were cultured on desoxycholate-citrate medium, MacConkey's medium, and by the brilliant-green enrichment technique, with negative results.

Post-mortem Examination (Dr. Vaux).—A fairly well nourished body; small scars of newly healed lesions on several fingers of the right hand. Heart moderately dilated; myocardium pale and flabby; a few petechiae on the posterior surface of the ventricles. Lungs showed considerable congestion. Stomach mucosa reddened; a little bile-stained fluid content. Mucosa of small intestine and caecum somewhat reddened; Peyer's patches not enlarged; no ulceration. Colon appeared normal. Liver (3 lb.) pale and friable; cut surface—pattern blurred. Gall-bladder contained thick dark

bile. Spleen (11 oz.) fairly firm; cut surface—dark red with conspicuous Malpighian bodies. Lymph glands: Two or three swollen glands in the transverse fissure of the liver. Urinary system and brain showed no abnormality. (Bone marrow not examined.)

Microscopical Findings.—Heart: Myocardium showed a moderate degree of fatty change and occasional focal necrosis. Liver: spleen revealed collections of mononuclear cells. Gram-negative bacilli were seen in small numbers in the spleen but not in liver. Some were found in the lymph glands.

Bacteriological Findings.—An organism of the *Salmonella* group was isolated from the heart blood, spleen, and liver, but not in cultures from the mucous surface of the small intestine.

Case II (M.H.G.W.)

A butcher's boy aged 18 was admitted to the Royal Bucks Hospital under the care of Dr. V. Lloyd Hart on Sept. 14, 1942, complaining of spasms of severe generalized abdominal pain which had been ushered in some three days previously by a vague feeling of malaise coupled with severe headache, constipation, and the vomiting on two occasions of some thin watery fluid. Previous to this he had always enjoyed perfect health. There was no one else ill in the house at the time, nor were there any other similar cases in the neighbourhood. No history of "food-poisoning" was obtained.

On admission he was febrile—temperature 104° F., pulse 90, respirations 20, somewhat confused—and he exhibited the characteristic anxious expression and incessant plucking at the bedclothes of the "typhoid state." The tongue was dry and coated. The abdomen was slightly distended and tender all over. The rectum was full of faeces. Apart from dilated pupils, nothing abnormal was found in the central nervous system or in the cardiovascular or respiratory systems. A provisional diagnosis of typhoid was made and the patient treated accordingly.

Progress.—Next day the abdomen was distended, constipation continued, and a few "rose spots" appeared on the trunk. The increased in number during the next two days, when, on the seventh day of the disease, a little fluid faeces was passed. His temperature had remained up between 101° F. and 103° F. It now rose sharply to 105° F., with pulse 120 and respirations 30, and the patient's general condition started to deteriorate. The following day he became incontinent of faeces, with much diarrhoea, and on the ninth day there was retention of urine followed by haematuria. The next day a crop of irregular pinkish blotches was observed on the dorsum of the hands and forearms. By the following day similar marks had appeared on the thighs, trunk, and face. This was the eleventh day of the disease, and he was now deeply unconscious, cyanosed, and almost pulseless, with temperature 103° F., pulse 140, and respirations 30. He died in coma a few hours later.

Laboratory Findings.—Blood cultures taken on the fifth and ninth days were incubated aerobically and yielded an organism of the *Salmonella* group. A catheter specimen of urine taken on the seventh day showed occasional pus cells in the centrifuged deposit and gave a moderately heavy growth of a similar organism. Agglutination reactions: The patient's serum taken on the ninth day showed no agglutination in dilutions of 1/40 or over with the Standards Laboratory (M.R.C.), Oxford, suspension of *Bact. paratyphosum* "H" and "O," *Bact. paratyphosum* "C" "H," polyvalent *Salmonella*, *Bact. typhi-murium*, *Bact. enteritidis* (Gaertner), *Bact. newport*, or with a formalized suspension of an 18-hour broth culture of the organism of the *Salmonella* group isolated from the patient's blood. Blood counts: Seventh day, W.B.C. 5,000 (polymorphonuclears 58%, lymphocytes 37%, monocytes 4%, eosinophils 1%); ninth day, W.B.C. 8,000 (polymorphonuclears 83%, lymphocytes 15%, monocytes 2%). No specimens of faeces were examined.

Post-mortem Examination (Dr. John Murray).—The body of a youth of about 10 st. with an irregular maculo-papular rash scattered over the face, trunk, thighs, and dorsum of hands and forearms. Right auricle dilated; numerous petechiae scattered over the visceral endothelium; marked haemolytic staining of the cardiac and aortic pericardium; heart muscle firm. Trachea showed acute inflammation, with a lustreless reddish-black leathery mucosa. A quantity of blood-stained jelly-like material was expressed from the bronchus. Oesophagus contained a little blackish vomit. Stomach normal. The small intestine and colon were grossly distended with gas and the lower part of the latter being slightly inflamed in one of fluid faeces, the mucosa of the latter being slightly inflamed in one or two places. The general appearance was not unlike that of a paralytic ileus. Liver normal. Spleen grossly enlarged and friable with complete loss of normal pattern. Kidneys: Right—typical early pyaemic kidney with recent infarcts; left—similar, but only slightly affected. (Brain and bone marrow not examined.)

Microscopical Findings.—Lungs: Advanced generalized bronchopneumonia interspersed with large areas of septic infarction.

Spleen: Marked congestion and endothelial overgrowth of a typical "septic spleen." Kidneys: Numerous small septic foci and areas of recent infarction.

Bacteriological Findings.—An organism of the *Salmonella* group was isolated from the spleen and lungs but not from the intestinal contents.

Bacteriology

The organisms of the *Salmonella* group isolated from the blood culture and from the spleen, liver, and heart blood at necropsy in Case I, and from the blood culture and urine and the spleen and lungs at necropsy in Case II, were identical, and showed the following characteristics:

Gram-negative bacillus: non-sporing; actively motile; grew well on simple laboratory media at 37° C., more slowly at 22° C.; aerobic and facultative anaerobe. Biochemical: Acid and gas in glucose, maltose, mannitol, rhamnose (24 hrs.), and dulcitol (late 7 to 10 days) on primary isolation. No change in lactose, saccharose, arabinose, trehalose, and salicin. Litmus milk, alkaline on the third day. Indole, negative. H₂S, positive.

Antigenic Analysis.—On primary isolation all strains from both cases were found to be in the non-specific phase. The specific phase of the organism was finally isolated after repeated passage in 0.3% agar to which non-specific serum (Kauffmann group E, titre 1:25,000) had been added, making a final concentration of about 1:50 serum. It was noted that a non-specific serum of the homologous (Kauffmann C) group did not result in the isolation of the specific phase. This method is a modification of that described by Craigie (1931). The antigenic analysis is: VI, VII; c; 1, 3, 4, 5. These organisms are therefore *Bact. cholerae-suis* (with one minor cultural aberration—the production of H₂S).

By definition, *Bact. cholerae-suis* var. *kunzendorf* exists only in the non-specific phase, whereas *Bact. cholerae-suis* is diphasic. So that, although all the strains from these cases on primary isolation were thought to be examples of the *kunzendorf* variety, the isolation of a specific phase showed that they were in fact *Bact. cholerae-suis*. Similarly, Gard (1937) states that he was able to isolate the specific phase from all *kunzendorf* strains he examined. Bruner and Edwards (1939) obtained similar results with eight *kunzendorf* strains, including two from the National Collection of Type Cultures (London) previously identified as such by Bruce White.

Discussion

The underlying pathological process in these sporadic cases of generalized infection with *Bact. cholerae-suis* or the *kunzendorf* variant is essentially a bacteraemia, often protracted, with a tendency to localization in the lungs, bones, or joints. Harvey (1937) notes that lung involvement, usually a bronchopneumonia, occurred in one-third of his series of 71 cases. Other lesions recorded there and elsewhere include meningitis, bacterial endocarditis, and pyelonephritis. Infections complicating surgical procedures, parturition, and occasionally tumours are also described.

Clinically, these cases are characterized by an acute onset of a typhoid-like infection with marked pyrexia, headache, anorexia, vomiting, and abdominal pain. Rigors and joint pains are not uncommon, and abdominal distension with generalized tenderness and a degree of muscle spasm has occasionally led to a fruitless laparotomy. In the majority of cases diagnosis depends entirely upon the isolation of the causal organism by blood cultures, which are often positive as late as the fourth and fifth weeks of the disease. The urine, too, should also be cultured; but the faeces have rarely given positive results, and then only late in the disease. In the early stages there is usually a leucopenia, later replaced by a leucocytosis, should localization of the infection occur. Agglutination reactions are of value from the second week onwards, and surprisingly high titres often persist for months or even years afterwards.

At necropsy there are usually a degree of splenomegaly, cloudy swelling of the liver and kidneys, and petechial haemorrhages in the serous membranes. Focal necrosis similar to that found in typhoid and paratyphoid fever is often seen in sections of the myocardium and the liver. For the rest, localization of infection produces lesions which in no way differ either

macroscopically or microscopically from lesions at similar sites due to other pyogenic organisms. The causal organisms can be isolated, often in pure culture, from these lesions as well as from the heart blood and the spleen.

Of the two cases presented in this paper, Case I is an example of an uncomplicated bacteraemia with death from toxæmia before localization of the infection had occurred. Case II is similar, but this patient lived long enough to develop lesions in the lungs and kidneys. In neither case was there any indication as to the source of infection or portal of entry. This is in agreement with the majority of published cases. With the exception of a few examples of consecutive infection in mother and child, and the occurrence of an isolated case on a farm at a time when the pigs were suffering from swine fever, little is known of the mode of infection in these sporadic cases.

The pig is the largest natural reservoir of these organisms, which are responsible for a paratyphoid fever in young pigs and are the commonest secondary invader in swine fever—a fact which led them to be regarded as the cause of this disease until it was later shown to be due to a filterable virus. Consequently, as Savage and Bruce White (1925) point out, since practically the whole pig is consumed, viscera and all, often in only a semi-cooked state, these organisms are probably ingested in man more often than any others of the *Salmonella* group.

The comparative rarity of generalized infections in man would therefore seem to be due to the inability of these organisms to establish themselves in the human host in the small numbers in which they are usually ingested, rather than to any lack of opportunity to do so. Once infection is established these organisms show towards their new host a similar degree of virulence to that shown to their natural host, the pig.

Summary

Two fatal cases of generalized infection with *Bact. cholerae-suis* are described. The cultural characteristics and antigenic analysis of the strains isolated from blood cultures, urine, and post-mortem material are given.

The general clinical and pathological features of this type of infection are described and the value of blood cultures in their diagnosis is stressed. The mode of infection in these cases remains obscure, but reasons are advanced for regarding their rarity as due to this organism's inability to establish itself in the tissues rather than to any lack of opportunity to do so.

We wish to express our thanks to Dr. J. L. Dunlop, County Medical Officer for Hertfordshire, for permission to publish Case I; also to Dr. V. Lloyd Hart and Dr. M. E. Roberts for the clinical notes, and to Dr. John Murray and Dr. D. Vaux for the post-mortem reports.

Blalock and Duncan have previously observed that a tourniquet applied to a severely injured limb for 5 hours much diminishes the chances of survival of the animal. They now show (*Arch. Surg.*, 1943, 46, 167) that cooling the part distal to the tourniquet lessens the ill effects of shutting off and then releasing the blood supply to an injured part. They suggest, therefore, that if it is necessary to apply a tourniquet to an injured limb (and it should be avoided if possible), the temperature of the distal, ischaemic, and anemic parts should be lowered artificially.

SYMPATHECTOMY IN TREATMENT OF THE
CRYOPATHIES

BY

E. D. TELFORD, F.R.C.S.

Emeritus Professor of Surgery, University of Manchester

(From the Neurovascular Clinic, Manchester Royal Infirmary)

The cryopathies include conditions such as frostbite, immersion foot and hand, trench and shelter foot. The inclusion of these lesions in one group is justified by the fact that their pathology is identical; they differ only in the degree of damage. While exposure to cold is no doubt the main factor, prolonged immersion must play an important part. Webster (1942) reports a series of cases, some of them gangrenous, which resulted from prolonged immersion in sea-water at 60 to 70° F.

The literature is already considerable. The subject has been fully discussed in recent important papers by Ungley (1942, 1943) and Greene (1942). These and other writers insist strongly that in the treatment of these patients the temperature of the damaged parts must be raised with extreme slowness and caution. A too rapid return to normal will be disastrous, especially if it be accelerated by any form of heat. Others have advocated sympathectomy in the immediate treatment. Against this suggestion is the fact that after rescue the chilled areas become notably hyperaemic, and it is in this stage that the local damage appears to increase or at least to become more obvious. It is not easy to see how a sympathectomy is going to act in tissues where so much damage to nerves is already present, and if it did act it could hardly be good practice to increase and prolong the stage of harmful hyperaemia. An analogy can be drawn from plant life. The gardener who has had the misfortune to have a delicate plant frosted would never dream of treating it by exposure to sun or raised temperature or by flooding with tepid water. He knows that his only chance is to withhold water and to maintain the plant under cool conditions, allowing the temperature to rise only with infinite slowness and patience.

The Sequelae and their Treatment

Although the majority of cases appear to make a good recovery with no, or at the worst trivial, loss of tissue, others continue to suffer from symptoms which are due to a combination of sclerosis and deficient blood supply. The after-troubles most often found are pain of a burning or tingling type increased by warmth and exertion, persistent indurated, swelling, chronic and very painful ulcers of pulps or extremities of digital stumps, loss of movement of fingers and toes, and occasionally a sensitization to cold which results in the Raynaud phenomenon. Hyperhidrosis may also be troublesome. These end-results are in fact those of vascular occlusion, and resemble closely those found in the more chronic types of thrombo-angiitis obliterans.

It seems reasonable, therefore, to hope that for these later troubles a sympathectomy may offer some prospect of relief. I have during the last five years had the opportunity of treating the later consequences of trauma from cold by preganglionic sympathectomy in five patients. In each of these cases a very gratifying relief of symptoms has been obtained. The patients were all men, of whom four were victims of frostbite—one in the hands and three in the feet—while the fifth was a negro seaman with grave damage to both feet from immersion. Brief notes of two of these cases are as follows.

Notes on Two Cases

Case 1.—A farm labourer aged 40 had the fingers of both hands frostbitten at his work. They recovered without loss of tissue, but at the end of eighteen months he was quite unable to work owing to chronic and very painful ulcers, together with a most troublesome Raynaud phenomenon. When seen in August, 1938, he could do no outdoor work because of the cyanotic attacks, and was suffering from pain and loss of sleep from chronic ulceration of the right index and left ring fingers. A bilateral preganglionic section of the cervico-dorsal chain was done in Sept., 1938. The result was immediately satisfactory. The circulation in the fingers improved and the ulcers healed. The Raynaud phenomenon, though not entirely abolished, was much reduced in frequency and severity. He has since been seen on many occasions, and remains well and in full work.

Case 2.—A negro seaman aged 24 was adrift in an open boat the North Atlantic during ten days in Nov., 1941. He was landed and was treated for six months in hospital in Newfoundland. In June, 1942, he was seen in this clinic, complaining of pain, ulceration, and inability to walk. Both feet were swollen, hard to the touch, and completely stiff. Tenderness and excessive sweating were noted. All the toes of both feet had been partially shed, and their stumps bore small chronic ulcers; the left fifth toe was gangrenous. He complained of constant burning pain, increased by warmth and attempts to walk. A bilateral lumbar-cord ganglionectomy was done by my colleague Miss Liebert in June, 1942, and resulted in immediate relief of pain, with rapid healing of the ulcers. The gangrenous toe did not improve, and was subsequently amputated, the wound healing readily. He has since continued well and gets about without pain.

These results would seem to indicate that sympathectomy is worth while in the chronic and painful sequelae of the cryopathies.

Conclusion

In the endeavour to estimate what benefit may result from the operation in any given case recourse may be had to preliminary tests of vascular efficiency—e.g., nerve block or foreign protein. In my experience the best method for the lower extremities is to use a thermo-couple thermometer provided with 8 or 10 leads, each carrying a point for application to the skin. These points are fixed on the areas selected for observation, and a movable plug allows the current from any one point to be recorded by the reflecting galvanometer. The temperatures are recorded with the patient on the theatre table, and at the end of half an hour's observation a temperature a spinal anaesthetic is given and the temperature again recorded. The normal rise in the feet in a young healthy adult is of the order of 8 to 10° C., but in cases such as those under discussion a rise of 1° C. would justify sympathectomy which can be carried out forthwith. In the upper limb general vasodilation may be employed, although it may be that, where all fingers appear equally affected, a simple block of the ulnar nerve at the elbow will give sufficient evidence.

MISUSE OF INTRAVENOUS N.A.B. FOR
VINCENT'S INFECTION

BY

ERIC C. O. JEWESBURY, D.M., M.R.C.P., D.P.M.
Acting Squadron Leader, R.A.F.V.R.

Ever since Ehrlich (1910) first reported the use of intravenous arsenic in the treatment of Vincent's angina arsenicals have continued to be advocated for this purpose. To-day, when both the available supply and the cost of such things deserve special consideration, it is worth while questioning the value of N.A.B. and its allies, particularly when given intravenously, in the treatment of this infection.

The disease, termed "trench mouth" in the last war, is a common accompaniment of wartime conditions, and the still seems to be a fairly widespread impression that in severe cases intravenous N.A.B. is the most potent method of treatment. Since N.A.B., in direct contact with the organisms, has a high spirochaetocidal power, it is at least logical to apply it locally to the lesions in the mouth. But Vincent's infection, unlike syphilis, is a purely local condition, and attempts to isolate fusospirochaetal organisms from the blood stream of infected patients have never been successful. Occasional reports of Vincent's infection occurring in patients undergoing antisyphilitic treatment have cast further doubt on the efficacy of intramuscular or intravenous arsenic in dealing with the lesions in the mouth.

Vincent's Angina after Intravenous Arsenicals

Thus, Sutton (1924) reported the case of a syphilitic woman who first developed Vincent's angina eleven days after starting intramuscular injections of sulpharsphenamine. She had many carious teeth, and direct smears obtained from typical lesions

her mouth showed numerous spirochaetes and fusiform bacilli. After regular cleansing of the mouth with hydrogen peroxide and local application of arsphenamine solution, the condition healed in a few days and the treatment for syphilis as continued. Hillsman and Driscoll (1925) similarly reported the case of a syphilitic woman who developed Vincent's infection nine days after arsphenamine injections. Local applications of arsphenamine alone gave no relief, though the condition subsequently healed satisfactorily. Williams (1929) described the case of another woman who developed Vincent's angina for the first time while undergoing antisyphilitic treatment with intravenous neoarsphenamine. Local treatment with sodium bichlorate was followed by rapid clinical recovery and disappearance of organisms. Donson (1933) described the development of Vincent's infection in a man, with considerable sepsis, who was having a course of intravenous injections of eosalvarsan and bismuth tartrate. Spirochaetes and fusiform bacilli were found in profusion in smears, and there were no symptoms suggestive of arsenic or bismuth poisoning. The condition responded immediately to local treatment. Eichmann (1926) has referred to a group of cases having had treatment for syphilis (neoarsphenamine intravenously and mercury intramuscularly) for at least two weeks previous to the first appearance of Vincent's infection. Successful relief of pain and healing occurred in a few days with local neoarsphenamine applications once a day and hydrogen peroxide mouth-washes every two hours.

Farrell and McNichols (1937) also state that they have had six patients who were receiving arsenical treatment for syphilis and who developed Vincent's infection. Goodridge (1942) has lately described a case of chronic Vincent's infection in a patient undergoing antisyphilitic treatment. Careful local treatment, including the application of 10% chromic acid, brought about rapid recovery, and smears for Vincent's organisms became negative.

Two Recent Illustrations

I have recently seen two airmen whose cases relate to this matter.

Case 1.—This patient (aged 26), whom I saw by courtesy of Squadron Leader J. V. MacGregor, was under treatment for syphilis. He had recently had a bad cold, and after his ninth intravenous injection of N.A.B. (when a total of some 5 g. had been given) he developed painful tender gums, which bled. Swallowing and chewing became very painful, and ulceration developed around the lower left molars and inner side of the left cheek. Vincent's organisms were found in a direct smear. He had a partially ruptured lower left third molar with a tender gum-flap, and there was some cervical adenitis and mild fever. He was put to bed and treated with applications of 10% chromic acid followed by hydrogen peroxide (10 vols.). He also received two-hourly mouth-washes of hydrogen peroxide and 300 mg. of nicotinic acid daily. The pain disappeared within 48 hours of starting local treatment and his improvement was rapid. The ulceration healed, and the partially ruptured tooth was in due course removed. Vincent's organisms were no longer found in smears, and his antisyphilitic course was able to be continued.

Case 2.—The second patient (aged 22) was admitted to an R.A.F. hospital on account of malaise and jaundice which had developed during antisyphilitic treatment. He had completed a first course of intravenous N.A.B. (total 5.55 g.) in Aug., 1942. He started a second course two months later, and had received a further 4.65 g. of his last injection being given on Nov. 12. On Nov. 14 he felt unwell, and on Nov. 16 was seen to be jaundiced. He was apyrexial at this time, had no sore throat, and there were no lesions in the mouth or any adenitis. On Nov. 20 a van den Bergh test showed 6 units of serum bilirubin. On Dec. 2 his temperature rose to 100.2°, and an acute ulcerative stomatitis, localized to the right side of the mouth, was present. There was an irregularly erupted lower right third molar, and some pocketing of the gums in this area was noted. The right submaxillary gland was enlarged and tender. A direct smear showed very numerous Vincent's organisms; there were no haemolytic streptococci on culture. He received local treatment with 10% chromic acid and hydrogen peroxide, as had the preceding case. Nicotinic acid was not given. The condition responded rapidly, and in two days the temperature was normal and the ulcerations were healing well. The tooth was removed on Dec. 10, and a smear taken on Dec. 18 showed no Vincent's organisms.

The interest of this case lies in the fact that a patient having had so much intravenous N.A.B. as to become jaundiced is

still able to harbour Vincent's organisms in his mouth and to develop ulcerative stomatitis. If the drug is so valueless prophylactically, scepticism as to the value of giving a single intravenous injection in the treatment of Vincent's angina becomes thereby even more justified.

Animal experiments lend further support to this view. Thus Rosebury and Foley (1939) produced local lesions in the groins of guinea-pigs by subcutaneous injections of material obtained from the mouths of patients with Vincent's angina. They state that "although intravenous administration of neoarsphenamine, under the conditions of these experiments, was ineffective in altering the course or character of experimental Vincent's infection, when the same drug was applied in direct contact with the flora there was a distinct ameliorative effect." In animals treated by the local method the exudate from the lesions became less and, microscopically, showed marked diminution in the number of organisms. On the other hand, the exudate from the lesions of animals treated intravenously showed no such decrease in its amount or in its content of Vincent's organisms; it in fact presented the characteristic picture obtained from untreated controls.

Methods of Treatment

It is a commonplace that fusiform bacilli and spirochaetes can be found in the mouths of many healthy people, and the causal relationship of these organisms to Vincent's angina has therefore been questioned. These and other anaerobes, however, are found in greater profusion in cases of poor oral hygiene, undernutrition, and chronic toxic or debilitating conditions. The so-called Vincent's organisms have therefore been aptly described as "opportunists" rather than primary pathogens.

Treatment of the disease calls primarily for treatment of the underlying condition, whether it be local or general. Nutritional deficiencies must also be remedied. Healing of the lesions in the mouth seems to be best accomplished by use of daily local applications of 10% chromic acid, followed immediately by hydrogen peroxide (10 vols.), and subsequent two-hourly mouth-washes of peroxide. In a recent series of investigations King (1943) has produced further evidence of the value of this form of local therapy, in combination with 150 mg. of nicotinic acid daily by mouth. This use of oxygen-liberating agents is a logical means of checking the growth of anaerobic organisms, and the rapid relief from discomfort is striking.

Periodontal treatment, including the cleansing of subgingival pockets, careful scaling, and removing of dental irregularities or sepsis at the appropriate time, is an important part of the treatment. It is said that Vincent's ulceration never occurs in edentulous mouths. The use of arsphenamine or allied compounds locally is at least a logical procedure, directed against the spirochaetes, although there seems to be little evidence that it is any more effective than the somewhat simpler and cheaper use of substances such as hydrogen peroxide.

Whatever form of treatment is given, however, it is to be hoped that the employment of intravenous arsenical compounds for this condition will be recognized as useless and wasteful. Hirschfield (1942) has recently referred to two instances in America "in which almost the entire hospital staff, including nurses and attendants, were subjected to a series of intravenous injections only because of 'positive' bacteriologic findings when they were examined after the appearance of a Vincent's infection in a nurse or one of the patients." Such a practice, quite apart from its prophylactic and therapeutic uselessness, is not without risk on account of possible idiosyncrasies to arsenic. Minor unpleasant effects are well known, but a very rare and severe form of reaction is an acute haemorrhagic encephalitis (or "encephalopathy"). Recent examples in syphilitics under treatment with arsenic have been reported by Nelson *et al.* (1943) and Halcrow (1943). Some 200 cases in all have been described, and the fatality rate is high. Smith and Newbill (1939) reported the case of a young man who was treated with intravenous neoarsphenamine and sulpharsphenamine for Vincent's angina. He developed severe reactions after both injections, became comatose, and died of arsenical myelo-encephalitis. It is said that 50% of these types of severe reactions occur after a second injection and that they

are more likely to occur in the presence of some active infection—of which Vincent's angina constitutes an example.

Conclusions

Vincent's infection sometimes develops in patients undergoing antisyphilitic treatment with intravenous arsenicals.

The use of intravenous arsenicals in the treatment of Vincent's infection is unsound, both on theoretical and on clinical grounds, particularly since the condition responds readily to other less expensive and less dangerous drugs.

I am indebted to Flight Lieut. S. C. Holms, R.A.F.V.R. (Dental Branch), for his help and advice.

A PHYSIOLOGICAL FACTOR IN HAEMOGLOBINOMETRY

BY

E. F. MCCARTHY, M.B., B.Ch., M.Sc.

St. Thomas's Hospital Medical School, Godalming

The recent Report to the Traumatic Shock Committee of the Medical Research Council on haemoglobin estimation (1943) fulfils its purpose admirably as a survey of methods including an analysis of technical limitations and suggestions for improvement. There is, however, a physiological factor in haemoglobinometry—namely, the diurnal variation—which merits the consideration of the physician. The blood haemoglobin may vary from increase or decrease of the total blood volume due to interchange of water with the tissues or to the withdrawal or addition of erythrocytes. Dreyer, Bazett, and Pierce (1920), on the basis of hourly or bi-hourly colorimetric haemoglobin estimations, assert that the haemoglobin may vary as much as 20 to 30% of the average throughout the day. Short (1934-5), using a colorimetric method, reported a variation of 17%. Price-Jones (1931) made 100 observations with a Haldane haemoglobinometer on blood obtained from his finger in the mornings and afternoons of successive days, and stated that there was no significant difference between afternoon and evening values. Rabinowitch (1923-4) used the oxygen-capacity method on 20 subjects, and reported a maximum variation of 26%. Photometric methods may be affected by the variation of substances in the blood other than haemoglobin, such as lipids, and the gasometric apparatus used by Rabinowitch was an early and not very accurate type.

Diurnal Variations in Hb Concentration

Some years ago, in an attempt to settle this question, I took part with Dr. van Slyke (1939) in an investigation of the diurnal variation in the blood of 18 normal men. Blood was obtained by venepuncture, with precautions to avoid stasis, at intervals of from two to three hours during the day. Haemoglobin was estimated by the CO-capacity method of van Slyke and Hiller (1928), which is superior to the oxygen-capacity measurement for reasons stated in the Medical Research Council report (1943). The mean difference between duplicate analyses of our samples was 0.06 vol. %, or 0.3% on the Haldane scale. The greatest range between highest and lowest values in an individual in the day was 2.3 vols. % CO (or O₂) capacity—i.e., about 12% on the Haldane scale. The average range was 1.3 vols. %, or 7% on the Haldane scale. Observations were repeated on each of five subjects on two separate days about a week apart, and there seemed to be a tendency for the blood of each subject to follow a course characteristic for that individual. It is difficult to make any generalization concerning the direction of the change apart from the statement

that there seems to be a tendency for the haemoglobin concentration to diminish during the day, but a subject who shows this change on one day gave the opposite result on another.

I have no reason to doubt that these findings represent real changes in the haemoglobin concentration of the blood. It seems that data of similar accuracy are not available for the alterations in women and children. The diurnal variations recorded in health may be greater in abnormal conditions. Moreover, the fact that the variations recorded by most of the earlier workers on blood samples obtained by pricking the skin are higher than those obtained by us inclines one to the belief that this difference may be due to local alterations in the concentration of haemoglobin, to the interference of lipid or other substances with the photometric technique, or, more simply, to sampling errors. Price-Jones (1931) found excellent agreement between gasometric measurements and colorimetric Haldane estimations in the blood of 20 subjects. It is clear, however, from his paper whether the colorimetric estimations were made on separate samples obtained by skin puncture or on the same samples used for gas analysis which were obtained by venepuncture.

Conclusions

Haemoglobin in the blood of normal men is subject to a diurnal variation which is less than that described by Rabinowitch and other workers but higher than that reported by Price-Jones. The average range is 7% in terms of the Haldane haemoglobinometer scale. The range of any diurnal variation which may occur in the haemoglobin of normal women and children appears to merit careful investigation.

Medical Memoranda

Arteriosclerotic Aneurysm of Abdominal Aorta with Perforation into Upper Jejunum

In contrast to aneurysm of the thoracic aorta, aneurysm of the abdominal aorta is comparatively rare, and its diagnosis might easily be missed for years, as in the case reported below. A few days before admission the patient was seen by a consultant, who thought of a growth in the sigmoid, but after the negative x-ray evidence, considered that a small polyp in the colon might explain the rectal haemorrhages. The long-standing rectal and vaginal pain was very likely due to the aneurysm. Very often in cases of abdominal aneurysm there is pain in the upper abdomen due to pressure on the coeliac plexus. Here there was a history of "fibrositis" of the upper abdomen, but her main and more permanent complaint was of the rectal and vaginal pain. The explanation of the difference from the usual upper abdominal pain may be that the situation of an aneurysm of the abdominal aorta is usually subdiaphragmatic whereas in this case it extended down to the bifurcation, might therefore be expected to exert pressure on the inferior mesenteric ganglion and so cause the pain referred to rectum and vulva. While the usual cause of thoracic aneurysm is syphilitic disease of the aorta, aneurysms of the abdominal aorta, at least in this country, are mostly due to arteriosclerosis, as it was in this case.

CLINICAL CASE RECORD

On Jan. 20, 1943, a lady aged 79 was admitted to the County Hospital, Odley. She had a long history of suffering. Seven years ago she was in bed for 6 months, and some form of heart disease was diagnosed. While in bed she developed a thrombophlebitis followed by neuralgic pains in the vulva and rectum. Nothing local was found that would explain this latter condition and no discharge or haemorrhage of any kind. A diagnosis of "vulvitis and rectal neuralgia" was made. These pains had persisted and increased up to the time of admission, and finally invalidated her to such an extent that she had to spend the last two years in bed. Four years ago she had had a short attack of "fibrositis" in the upper half of the abdomen and in the lumbar region. Fourteen days before admission she had an unheralded rectal haemorrhage. At first she passed blood mixed with faeces and then pure blood-clots. She lost a

amount of blood. These haemorrhagic motions numbered six or eight daily, and continued up to the day before admission.

The patient was mentally alert but physically in poor shape; the slightest movement exhausted her. She was very pale and emaciated. Her peripheral arteries showed an extraordinary degree of arteriosclerosis even for her age. Pulse, respiration, temperature, and reflexes were normal. The heart showed signs of enlargement towards the left, and a systolic murmur was audible over the aortic valve.

In the upper part of the abdomen, just to the left of the midline, a tumour was palpable, approximately the size of a fist, showing expansile pulsation. It was easily possible to grasp this tumour in the examining hand, and its mobility was strictly limited to a slight lateral movement. A systolic murmur was audible on auscultation. The rest of the examination showed no abnormality. The blood pressure was 160/60 mm. Hg. The Wassermann reaction was negative.

A barium meal and enema had been given outside a few days before her admission to hospital, but failed to show any abnormality. After six days in this hospital she had a haematemesis early in the morning and died a few minutes later. The clinical diagnosis was aneurysm of the abdominal aorta, with rupture into the small intestine. Permission for an abdominal necropsy was granted, and the findings were as follows.

POST-MORTEM EXAMINATION

Advanced atheroma and arteriosclerosis. Kidneys rather smaller than normal and arteriosclerotic. A large sacular aneurysm protruded from the anterior and left aspect of the abdominal aorta immediately deep to the pancreas, which was stretched over its anterior surface. The aneurysmal dilatation measured about 4 in. by 2 in. by 2 in. A portion of jejunum was firmly adherent to the anterior surface towards its right side, and it was evident from blood in the intestine that a communication existed between the two. The aneurysm was not adherent to any other viscus. It was obviously of very long standing. The other abdominal organs were normal. A specimen consisting of the aneurysmal sac, with immediately adjacent pancreas and the adherent portion of jejunum, was sent to the County Laboratory, Wakefield, from which source the following report was received:

"On the lower portion of the abdominal aorta, and on the anterior wall, there is a large sacular aneurysm. The mouth of the sac is oval and large, and involves two-thirds of the entire circumference of the aorta. The mouth of the sac measures 7 cm. in length and 5 cm. in width, and the lower edge is situated 1 cm. above the bifurcation. The sac contains much laminated thrombus, which is fairly firmly adherent to the wall. On removing this thrombus the true shape of the sac is observed. The greatest depth is 4 cm. from the mouth, and the base shows minor sacculations. The deepest (most anterior) is on the left side in an antero-lateral direction. At this point the wall is thinned over an area roughly oval (2 by 1.8 cm.) and covered by more recent softer thrombus. There is a communication between the upper part of this sacculi and the overlying adherent jejunum. The communicating aperture is small and probably measured less than 5 mm. during life. The jejunum itself is normal and is adherent to the outer aspect of the sac, to which it forms an adventitious coat. The aorta shows atheromatous changes generally and the aneurysm is essentially of the atherosclerotic type—partially dissecting at the point of rupture."

My thanks are due to the medical superintendent, Dr. J. Norman Hill, for doing the necropsy, and for permission to publish this case; and to Dr. P. L. Suteland, county pathologist, and Dr. R. M. Hezlie of the Public Health Laboratory, Wakefield, for examination of the specimen and advice to publish.

WALTER HAUSMANN, M.D., Vienna,
R.M.O., County Hospital, Oley, Yorks.

The Medical Division of the Office of Civilian Defence in Washington has recently (July 10, 1943) issued new regulations on the treatment of burns and wound infections in air-raid casualties. When abdominal viscera are perforated the revised pamphlet recommends sodium sulphadiazine as the drug of choice for parenteral administration, this being considered preferable to oral therapy during the first 48 hours. Attention is drawn to the danger of giving sulphonamide drugs to a patient who is not excreting over 1,000 c.cm. of urine a day. If output of urine is inadequate and sulphonamide therapy is required, the urine should be examined for evidence of renal damage and the dose of the drug so adjusted that the blood concentration, determined daily, does not exceed 10 mg. per 100 c.cm. If urinary output continues to fall administration of the drug should be stopped, and fluid should be forced orally or given intravenously. If anuria results, owing to bilateral obstruction of the ureters, ureteral catheterization and lavage of the renal pelvis may be required. The revised O.C.D. pamphlet no longer recommends the use of ointments or jellies containing tannic acid in the first-aid treatment of burns. If expert treatment cannot be carried out within two hours it is advised that the patient should be given sufficient morphine to relieve pain, and that the burned surface should be covered with sterile boric acid ointment or petrolatum, over which one or two layers of gauze of fine mesh is to be smoothly applied. Over this is placed a dressing of thick sterile gauze or sterile cotton-waste, and the whole dressing is to be bandaged firmly but not tightly. As an alternative, a jelly containing 5% sulphathiazole in water-soluble base is permissible.

Reviews

OCCUPATIONAL DISEASES

Outlines of Industrial Medicine, Legislation, and Hygiene. By James Burnet, M.D., F.R.C.P.E. (Pp. 87. 7s. 6d.) Bristol: John Wright and Sons; London: Simpkin Marshall.

This small book attempts within the compass of 83 short pages to deal with three interrelated subjects, and, although in his preface the author makes no greater claim for it than that it should serve as an introduction, the title is an ambitious one. The book deals mainly with occupational diseases, the subject of hygiene being relegated to the last six pages. Chapters VI to X form the second part of the book and deal in some 22 pages with such subjects as the history of factory legislation, Workmen's Compensation Acts, the Truck Acts, the Factories Act, 1937, and incapacity for work, but these chapters are in the form of short annotations rather than of attempts at careful elucidation.

It is generally agreed that the study of occupational disease can best be made against a background of industrial hygiene, and the purpose of this publication would have been better served if the first part had been devoted to those factors of hygiene which have a special significance in industrial life. Few authorities will agree with the unqualified statement in the preface that "hygiene in factories differs very little from the hygiene of ordinary premises." The principles of hygiene may be the same, but there is a more detailed application of these principles in industry, and the directions of such application might with advantage have been stressed.

Nearly three-quarters of this manual are devoted to occupational diseases, and of this section more than one-half to poisons. The 28 pages dealing with industrial poisons are probably the best of the book, and the author, who was formerly an examiner in materia medica and therapeutics of Aberdeen University, can speak authoritatively. The chapters dealing with medical diseases contain all-too-brief references to the pneumoconioses, while in regard to silicosis the author takes no cognizance of the work of W. R. Jones, who, working in the Rand, demonstrated the importance of the fibrous silicates like sericite in the production of the disease quite apart from silicosis due to free silica.

There is a striking absence in the book of reference to such important questions as the psychoses and neuroses of industry, except in regard to occupational cramps, and the description of miner's nystagmus omits any reference to the psychoneurotic element in the later stages of the disease. Throughout the book there is no mention of the existence of accident-proneness or other factors in the production of accidents—subjects which to-day are so important. If the main intention of the book is to provide the general practitioner who occasionally sees a case of occupational disease with a handy book of reference the intention may have succeeded, more especially as it sets out in annotated form the main provisions of factory legislation which would be useful to him. When the next edition is prepared, which no doubt it will be in the near future, we suggest that the author might increase its size and incidentally its value.

ELECTROCARDIOGRAPHY

Electrocardiograms. An Elementary Atlas for Students and Practitioners. By H. Wallace Jones, M.D., M.Sc., F.R.C.P., and E. Noble Chamberlain, M.D., M.Sc., F.R.C.P. Second edition. (Pp. 56; illustrated. 5s.) Bristol: John Wright and Sons; London: Simpkin Marshall, 1943.

The Electrocardiogram and X-ray Configuration of the Heart. By Arthur M. Master, B.S., M.D., F.A.C.P. Second edition, enlarged and thoroughly revised. (Pp. 404; illustrated. 36s.) London: Henry Kimpton.

The first of these two books gives a valuable grounding for students in the interpretation of the electrocardiogram. The explanation of the mechanism of the machine is simple and to the point. The significance of the various normal complexes is clearly described. Technically the illustrations are excellent and well marked. The modern physician uses the cardiograph very largely in the diagnosis of myocardial disease, and for every tracing taken for an arrhythmia at least a dozen are taken when the rhythm is normal and only the condition of the myocardium is in question. It is perhaps surprising that

The authors devote so much space to the arrhythmias—eighteen pages—while only twenty pages have to include all the other abnormalities. The section on coronary thrombosis is pretty comprehensive, but the chest leads are not always included. The R-S-T changes in the chest leads might well be better emphasized. In anterior infarction the significance of deep Q4 and absent R4 is not mentioned, though illustrations showing these changes are printed. The tracings of posterior infarction show more T₁ and T₂ changes than is usually regarded as typical. The section on right and left ventricular preponderance does not distinguish between simple axis deviation and ventricular hypertrophy. So much has been written recently on ventricular strain changes in the cardiogram that the lack of reference even to hypertensive heart disease is noticeable. Angina of effort depends for its objective signs so often on the cardiogram alone. This book provides one tracing only of chronic coronary disease and does not helpfully correlate these changes with the changes of cardiac infarction. In spite of shortcomings, largely due to keeping the book brief, simple, and concise, this atlas will get the student and medical practitioner over the difficult initial stage of understanding the electrocardiogram. It should stimulate the student to continue the study of electrocardiography.

The second edition of Dr. Master's book has now become complete as an x-ray monograph on the heart. Written originally to instruct in the interpretation of the electrocardiogram, this edition has become a reference book in the radiological configuration of all varieties of heart disease, unique up to the present date. It is now an essential in every cardiologist's library. The book is made up of approximately 50 radiographs of varieties of heart disease, each one with the electrocardiogram on the same page. A short note on the condition with a description of the essential changes in the radiograph and cardiogram is printed on the opposite page. It is not just an atlas of cardiac radiology and electrocardiography; each section has a concise, well-referenced account of the subject to be illustrated in the succeeding pages. The knowledge of x-ray and cardiographic technique is excellent. A part of the book is devoted to varieties of non-pathological conditions. Illustrations are given of the heart in childhood, in young adults, in middle age and in old age, in obesity, in pregnancy, and during change of posture. The section devoted to pathological conditions contains nearly all the varieties of known heart disease. The section on congenital cardiac abnormalities is of particular value. The section on pulmonary disease, emphysema, pulmonary embolism, pneumothorax, and in deformities of the thoracic wall is most thoroughly and clearly described. Radiographs showing contrast visualization with diodrast will encourage further research in this new branch of x-ray diagnosis—some fine illustrations are reproduced. The only deficiency from the x-ray aspect is the small amount of information on the heart and lung fields in failure, and the change in the heart size which may occur when failure has passed. The electrocardiograms shown are clear, and the standard limb leads with I, II, III, aVR, aVL, aVF, and CF, chest leads are taken in nearly all cases. It might be criticized that the value of right pectoral, right arm lead (CR₁) is not mentioned in diagnosis of right ventricular strain. The section on the electrocardiogram in acute disease is of considerable interest and provides information not easily found elsewhere. The bibliography and reference index are excellent. This book will be widely read by those interested in heart disease.

PSYCHOPATHOLOGY

Psychopathology: A Survey of Modern Approaches. By J. Ernest Nicole, L.M.S.S.A. Third edition, revised and enlarged. (Pp. 265. 15s.) London: Baillière, Tindall and Cox. 1942.

The third edition of this compendious work appears with additions to most chapters. Its scope is surprisingly wide and inclusive; the references alone amount to 28 pages. Naturally where so much is compassed critical appraisal of the different views summarized is hardly possible, so that the main effect is to stimulate the reader to pursue his own explorations of the literature in new directions rather than to give him much information about the direction which is likely to be most profitable.

The author is too modest to think that anyone could assume the role of mentor to another in so many different fields covered by this volume. Some will think that certain schools of thought have been given undue prominence, but this is perhaps as much a matter of taste as of scientific judgment. The book serves the very useful purpose of emphasizing the great diversity of approaches which exist to the problems of psychological medicine and the remoteness of the hope of finding a master mind which will be able to synthesize them all.

Notes on Books

The Oxford University Press has published as a sixpenny pamphlet a sermon entitled *Cleanse the Leper*, preached by the Rev. P. B. Clayton to members of the University of Oxford on behalf of the British Empire Leprosy Relief Association.

No. 1 of the Research Supplements to the *International Journal of Psycho-Analysis*, edited by Dr. Edward Glover, is *A New German-English Psycho-Analytical Vocabulary*, by ALIX STRACHEY. This is essentially an enlarged and revised edition of a glossary which appeared in 1924; it is designed for the practical purpose of helping translators of psycho-analytical works, and is published for the Institute of Psycho-Analysis by Baillière, Tindall and Cox at 10s. 6d.

The *Index to the Literature of Food Investigation*, Vol. 14, No. 2, dated September, 1942, and issued by the Department of Scientific and Industrial Research, has now come to hand. The items covered are Nos. 488 to 982 inclusive, and there is an index of authors. An editorial note states that because of the urgent need for economy in paper those who wish to obtain the *Index* regularly must place orders in advance with the Sales Office, H.M. Stationery Office, York House, Kingsway, London, W.C.2, or with any bookseller.

The Association of Scientific Workers (73, High Holborn, W.C.1) has published at 2s. 6d. under the title *Planning of Science* a full report of the proceedings of the conference held last January in Caxton Hall. There were three sessions—one concerned with central direction of science, one with local organization, and the third with the future of science.

Preparations and Appliances

WALKING "IRON" FOR LEG PLASTERS

MR. C. DENLEY CLARK, F.R.C.S.Ed., writes from the Memorial Hospital, Shooter's Hill, S.E.5:

Major Stamm's description of the new walking iron for short leg plasters (*Journal*, July 3, p. 13) stimulates me to describe a device which we have been using. Made of wood 1½ inches thick, it is as wide and as long as the plaster foot, and its shape in side view is shown in Fig. 1. From this it will be seen that the top surface of the foot-piece is slightly hollowed longitudinally. The anterior half of the lower surface curves steeply. The heel is flat and there is a rectangular notch in the lower surface to accommodate plaster bandages for fastening the device on to the foot.

Fig. 2 shows the method of applying plaster and rocker. The plaster is reinforced at A in the lower part of the shin above the ankle, to avoid cracking; the posterior plaster slab (B) is continued under the foot. The foot-piece is preferably applied while the plaster is wet. The plaster should be padded over the upper part of the shin (C) to avoid possible pressure-sores.

This device is light and very easily made from odd pieces of timber. Being only 1½ inches thick, it can be used for above-knee as well as for below-knee plasters. The flat heel gives stability and comfort for standing. The curved anterior part permits of heel-to-toe action in walking. The patient can thus rock along in any weather. We call this appliance "the rocker."

STIMULATION OF LEUCOPOIESIS

A satisfactory stimulant to leucopoiesis would have many uses, and it is no wonder that a diversity of compounds has been introduced for this purpose. A few of these, such as manganese butyrate and the pentose nucleotides, have achieved more than passing popularity, but there is little evidence that any of them produces an enduring leucocytosis. They act mainly by redistribution and mobilization of preformed leucocytes. Of the many substances tested by Das Gupta,¹ only colchicine stimulated the proliferation of cells in the marrow, and the toxic effects of this drug outweighed its advantages. Recently, however, Zondek and Bromberg² have reported the production of a leucocytosis with *p*-chloro-xylenol dissolved in methyl acetamide, which appears to be sufficiently promising to justify a more extensive therapeutic trial. The discovery was made while studying the chemotherapeutic properties of the halogenized phenols. In the course of this work, while testing the solubility of *p*-chloro-xylenol in various substances, it was noticed that methyl acetamide, unlike the other solvents, caused a moderate leucocytosis of short duration when given intramuscularly. This was much amplified when the solvent was combined with the *p*-chloro-xylenol. The leucocytosis was accompanied by the appearance of immature myeloid cells in the circulation, which suggested increased activity of the bone marrow. Further tests showed that *p*-chloro-xylenol alone had no effect, but that when it was dissolved in methyl acetamide the leucocytosis produced was more evident and better sustained than when the solvent was given alone. The effect appeared to be directly proportional to the content of *p*-chloro-xylenol.

This formed the basis for a more extensive trial with a 25% solution of *p*-chloro-xylenol (25% C.X.M.). Seventeen normal subjects received 50 c.cm. of this material over a period of three days, and were found to have a leucocytosis which began at 24 hours and lasted 10 days. The granulocytes were increased fourfold, and maximal counts of 20,000 per c.mm. were obtained. The material was also tested in four cases of typhoid, a disease particularly resistant to chemotactic substances. When 56 c.cm. of the 25% C.X.M. was given over a five-day period a leucocytosis of over 12,000 per c.mm. was obtained in each case, but it was maintained only 36 hours after the last injection. Four other cases, with local infections accompanied by a leucocytosis, were tested, and the authors claim that in these the response was quicker than in the normal subjects. A case of pyelitis is cited in which the leucocytes increased from 9,200 to 38,000 per c.mm. This admittedly a small series, but the authors have published their results in the hope that the drug will be given further trial in neutropenic conditions.

A different approach to the subject has been made by Menkin, who has published a series of experiments in which he has demonstrated the presence of a leucocytic or (L.P.F) in inflammatory exudates. Following an initial series of experiments in which he produced a discharge of immature polymorphs into the circulation by injection of various inflammatory exudates, Menkin has

made a series of chemical studies which have led him to identify the activity with a thermolabile, non-diffusible substance which he believes to be a pseudo-globulin. Recently he and Kadish³ have obtained this substance in a desiccated form. When dissolved in saline and injected by cardiac puncture into dogs, the powder caused an increase of 50 to 160% in the circulating leucocytes, which was considerably greater than the normal range of variation of 12 to 80%. With one exception a similar effect followed subcutaneous injection, but the maximum rise occurred later than with intracardiac injection. In earlier tests with this powder there was a transient leucopenia after injection, but this did not occur later, when the substance was prepared after initial removal of the euglobulin and albumin fractions from the exudates, and the leucocytic effect was even more potent than in the earlier tests. No clinical trial has as yet been made.

Working in a similar field, Turner and Miller⁴ claim to have obtained two biologically active materials from the urine and faeces of human patients with leukaemia which will produce specific myeloid and lymphoid hyperplasia respectively when injected into guinea-pigs. In 1940 Miller described myeloid hyperplasia in the bone marrow, liver, spleen, and other organs of 33 guinea-pigs after injection of concentrates from the urine of patients with chronic myeloid leukaemia. The changes were not accompanied by any increase in the circulating white cells. Since then he and Turner have subjected to repeated fractionation the urine of patients with lymphatic, myeloid, and monocytic leukaemia, as well as with Hodgkin's disease and lymphosarcoma. They have obtained two separate extracts, one containing a carboxyl group which produces a specific myeloid hyperplasia resembling that described in the original experiment, and one containing a carbonyl group which produces a specific lymphatic hyperplasia of the tissues. They further claim to be able to convert the one extract into the other, and suggest that they are closely related chemical substances which are always excreted in these diseases. As leukaemia, like cancer, is not transmissible from one species to another, we are probably justified in regarding these results also as the purely pharmacological effects of tissue extracts. Further knowledge of the chemistry of these extracts will be awaited with interest.

INADEQUATE HOSPITAL DIETS

The idea that diet should be one of the remedial services offered by hospitals has been late in arriving. Not very long ago it was the custom for the diet of in-patients, prescribed according to a rigid and primitive schedule or scale, to be supplemented by "extras" brought in by friends, and the question whether at the early breakfast, often taken at 6 a.m., an egg was added to the tea and bread and margarine depended upon such casual provision. The result was that patients not so assisted from outside might actually go short of food; others had too much for their needs at other meal-times. For a large proportion of patients the diet—such as it was, "full" or "light"—depended on the whim of a house officer ignorant of dietetics and given a free hand by his chief. There was special provision for nephritis, diabetes, and some other diseases, but, generally speaking, in those days nobody seemed to mind what the ordinary patient ate except the patient and perhaps the sister. The few physicians and surgeons who cared for such things were thought to be rather cranky by their colleagues, though students seemed anxious to learn, realizing that guidance would be expected

¹ *Ind. J. med. Res.*, 1939, 26, 647.² *Amer. J. med. Sci.*, 1943, 205, 62.³ *Amer. J. med. Sci.*, 1943, 205, 363.⁴ *J. Biol. Chem.*, 1943, 147, 573.

from them in private practice. Proof of a growing interest in the subject was given by the frequent appearance of reprints and new editions of Robert Hutchison's *Food and the Principles of Dietetics*, first published in 1900. As the author said in his preface to the first edition, the very gratifying reception accorded to these lectures to students of the London Hospital and the almost total neglect of the subject in ordinary medical education induced him to publish them in book form. This pioneer work and the enormous developments in knowledge of nutrition have borne fruit, so that there are few practising doctors to-day who are not food-conscious and alive to the significance of diet in health and sickness.

It is now becoming realized that the hospital kitchen is at least as important as the hospital dispensary, and a number of hospitals are employing dietitians. In the area of King Edward's Hospital Fund for London dietitians have been appointed in about 12% of hospitals, but in too many of these the dietitian is looked upon as a person concerned only with the comparatively small number of special diets and is not consulted about the standard of feeding in the general wards. The King's Fund has lately issued an interesting but rather disquieting memorandum¹—disquieting because it suggests to those who did not know this already that, in spite of recent improvements, including the later breakfast, hospital diet is not all it should be in quality and quantity, in nutritional standard, and in methods of preparation and service. Particulars are given in this memorandum of a survey of the diet provided for patients and nursing staff at three general hospitals of moderate size in widely separated parts of Greater London. Samples of the diet were collected and analysed each day for one week, and the results in terms of nutritive value are set out in tables. In the case of patients lying in bed little more than the basal metabolic requirements of energy are expended, and something like 1,690 calories as the daily need for an average man and 1,450 for a woman have been suggested. On this basis, in only one of the three hospitals were the food supplies adequate. In the other two the daily average of calories was, for male patients, 1,420 and 1,260, and for female patients, 1,150 and 960. At two of the hospitals the supply of protein was not up to standard, and at one the diet was deficient in calcium and iron. None of the diets appeared to reach the desired levels for vitamins A and C. The Technical Commission of the League of Nations suggested 30 mg. of vitamin C daily as necessary for health, and many authorities consider this figure too low; but at one of these hospitals the daily average was 3 mg., at another 5 mg., and at the third 13 mg. for male patients and 10 for female. As for nurses' meals, if the energy requirement of a moderately active woman be taken as 2,500 calories a day, the staff at one of these hospitals was not getting enough to eat; in none of the hospitals were adequate amounts of vitamins A and C provided in the nurses' bill of fare, and in one the iron in the diet was below the desired level. The King's Fund Subcommittee, of which Sir Charlton Briscoe is chairman, suggests a permanent committee for catering and diet in every hospital. This committee would co-ordinate the responsibilities of the catering officer or purchaser and the choice of food-stuffs advised by the dietitian. Other recommendations are that small hospitals should be grouped for central buying, that an endeavour should be made to attract first-class cooks to hospitals by offering more adequate salaries, and that ward sisters should be encouraged to regard the service of suitable and appetizing meals as a most important part of their responsibility. The job of the

dietitian should be to plan the dietary as a whole to meet nutritional standards prescribed by the medical staff. As Sir Alfred Webb-Johnson said at the recent conference on hospital meals, reported in our issue of August 7, the dietitians should have control not only of their own special kitchens but of the general hospital kitchen as well. Common sense and knowledge of human nature tell us it is not enough to plan a diet, for the best planning may be ruined by poor cooking, and good cooking may be ruined by lax service. The dietitian should consider it part of her duty to supervise or advise on the methods of cooking and the manner in which the meals are served to patients.

The King's Fund has rendered many signal services to hospitals, apart from financial help, and it proposes for itself another—namely, to give dietetic guidance to voluntary hospitals in the London area which express a wish for it. A good suggestion is that the Fund's dietetic adviser might spend two or three weeks at a hospital by invitation, surveying the dietary and the methods of cooking and serving, and then offer such advice as seems necessary and expedient.

TREATMENT OF LUPUS VULGARIS

Lupus vulgaris has always been the Cinderella of the tuberculosis services, but there are signs that at last the public conscience is beginning to be roused by the unjustifiable state of affairs in relation to the treatment of this disease. There are several reasons for the neglect which sufferers have had to bear. In the first place lupus is seldom a fatal complaint; it lasts for many years, and the patients usually die from some quite different malady. It has even been remarked that they seldom develop visceral tuberculosis, for the skin in some way seems to defend the internal organs from tuberculous infection. It does not give rise to much acute physical pain or even actual physical disability. Moreover, the sufferers from lupus vulgaris are not, fortunately, a very numerous body in this country, and hence their champions have hardly been vocal enough to catch the ear of the body politic. For the most part they are drawn from the more impecunious strata of society and therefore do not much attract the attention of the specialist engaged in private practice. The result is that those afflicted with lupus often fail to get the benefit of the modern methods of treatment to which they ought to be entitled. On the other hand, lupus is an exceedingly chronic and obstinate affection, difficult to cure even when skilfully handled and, since it most commonly attacks the face, very prone to cause the most hideous disfigurement, making its victims unable to mingle on equal terms with their fellows. The fact that such a disease is not treated with all the means that modern science has put at our disposal is a national disgrace. Probably the chief reason for this deplorable state of affairs is financial. Lupus vulgaris is one of the most expensive diseases there is to treat, and local authorities have been reluctant to face the cost. Light-treatment is the sheet anchor of lupus therapy, and since the introduction of the Finsen and the Finsen-Reyn lamps nearly 40 years ago nothing has been discovered to take their place. They are exceedingly costly appliances to run because each patient needs the undivided attention of a skilled nurse during every session of his treatment. Consequently to keep a single lamp in action day in and day out requires the whole time of one trained nurse, and the average yearly cost of a nurse, including maintenance and lodging, must amount to at least £200 to any institution. Not many patients can be dealt with by a single lamp. Many attempts have been made to avoid the necessity for this expensive form of treatment but with-

¹ Published by Geo. Barber and Son, Ltd., Fumival Street, London, E.C.4. (6d. post free.)

out success. General light baths, which are a most useful adjunct, are quite inadequate as a substitute for the concentrated local application of ultra-violet light by the Finsen method. In addition to the properly administered light-treatment the patients require adequate provision for their maintenance and occupation during its continuance. If children, they must be educated; if adults, they must be employed.

These aspects of the problem have recently been given some attention by contributors to the *Bulletin of the National Association for the Prevention of Tuberculosis*. Dr. F. S. Airey stresses the need for special lupus treatment centres to deal with the cases (he reckons that at least four centres would be required for England and Wales alone); while Sir Henry Gauvain, who has had a lifelong experience in treating all sorts of tuberculosis, including lupus, points to the advantages of carrying out the treatment in a highly specialized residential institution where the services of ancillary specialists—e.g., rhinologists and plastic surgeons—are available as required. Advanced cases in adults should be cared for in a colony where their medical, economic, and social needs can all be met. It is easy to see that Dr. Airey's and Sir Henry Gauvain's ideas should be combined. At the present time perhaps the Finsen Institute of the London Hospital, founded by Queen Alexandra in the early years of this century and organized and developed with great skill and energy by Dr. Sequeira, puts their plans into practice more nearly than any other institution. All the medical skill is certainly there, but it is impossible for a voluntary hospital, however enterprising, to cater for the economic and social needs of patients who may need treatment extended over many years, as lupus patients often do. Such a task can be undertaken only by those who have the resources of the State behind them. There are now indications that in the near future the whole tuberculosis service of the nation will undergo an overhaul. That will be the opportunity to put the treatment of lupus on a proper basis.

INFANTILE ENTERITIS AND BREAST-FEEDING IN DUBLIN

Dr. C. J. McSweeney's report for 1942 as medical superintendent of Cork Street Fever Hospital, Dublin, includes among other matters of interest a section on enteritis and gastro-enteritis in infants, which was for the second year in succession abnormally prevalent in the City of Dublin. Again the disease fell most heavily on infants under 1 year of age, and was especially fatal in the early months of life. Most of the cases came into hospital during August and September, but the peak mortality month was November. The outstanding fact is that nearly 90% of these infants admitted to the wards were bottle-fed. In all, 174 cases were treated, with 75 deaths—a case-fatality rate of 43.1%, compared with 40.7% in 1941. "There can be no doubt," writes Dr. McSweeney, "that this is by far the most fatal infectious disease affecting infants." Of the 174 children, 141 were under 1 year of age, and 65 of those died. Of 19 infants aged 1 month and under, 18 died. Only two of the 75 babies dying of gastro-enteritis were over 1 year of age. Vomiting was very rare after the acute stage; green stools persisted for weeks and sometimes months with a normal temperature. Toxaemia was completely absent, but a steady loss in weight took place with development of dehydration. Bacteriological investigations, except for a few cases in which *B. proteus* was isolated from the faeces, were negative. Early in the epidemic sulphaguandine treatment was tried; in all, 72 unselected cases had it. Of the babies given sulphaguandine, 36 (exactly 50%) died, compared with 102 not receiving the drug, of whom 39

died (38.2%). With regard to the fatal cases treated by this or other means, necropsy revealed haemorrhages into the mucous membrane of the small bowel, which were most intense in the ileum. Haemorrhages were also seen in the stomach and duodenum. The correct name for the disease would therefore appear to be gastro-enteritis, though gastric symptoms were confined to the early stages. Dr. McSweeney regards this highly fatal condition as a new clinical entity, for which so far no effective treatment has been found. The aetiology being uncertain, preventive measures for elimination of the disease cannot be finally postulated; but enough is known to lower the incidence very materially. "If all infants could be breast-fed for at least the first three months of life about 200 infants would be saved in Dublin each year. If the breast-feeding could be continued for six months gastro-enteritis as a public health problem would disappear." Dr. McSweeney urges doctors in private and dispensary practice, and especially those with large midwifery lists, and also the social workers who visit the homes of the Dublin poor, to support the activities of the maternity and child welfare authorities and the staffs of maternity hospitals in advocating breast-feeding throughout the first six months of a baby's life. But more is needed. The development of this disease in a young baby is, in Dr. McSweeney's experience, very often the direct outcome of economic conditions in the household which have caused malnutrition of the mother with a consequent failure of lactation.

DEMEROL

In 1939, in the course of a search for substitutes for the atropine series of drugs, Eisleb and Schaumann¹ reported the synthesis of the ethyl ester of 1-methyl-4-phenylpiperidine-4-carboxylic acid. This substance was originally named "dolantin" by its discoverers. It was soon shown that in addition to possessing a slight atropine-like activity, it produced also a marked morphine-like response, and it was recommended as of possible therapeutic use as an antispasmodic and analgesic. Its pharmacological actions have been studied in this country by Duguid and Heathcote,² who have confirmed its antagonism to the effects of acetylcholine on the heart and intestine; its action in this respect, however, appears to be much weaker than that of atropine. A number of clinical reports on the usefulness of the drug have also appeared, and Battermann³ has lately produced an analysis of its use in 1,119 cases presenting pain due to a variety of surgical and medical conditions. The responses of the patients to the drug, now known in America under the name of "demerol," were carefully graded, attention being paid to the psychological make-up of the subject—a point of considerable importance in work of this kind, where much of the data has of necessity to be obtained by close questioning of the patient. According to Battermann, post-operative pain is most easily controlled, though excellent results were also obtained in non-operative surgical and medical conditions. In colicky pain of biliary, renal, or gastro-intestinal origin it is thought that the antispasmodic action of demerol contributes to its analgesic properties. After parenteral administration, either subcutaneously or intramuscularly, it is claimed that the analgesic effect is apparent within 15 minutes; when administered orally the effect is less rapid and less dramatic. It is necessary to give the drug in somewhat larger doses than those of morphine, but as it appears to be relatively free from any serious toxic manifestations in therapeutic doses this is not regarded as a disadvantage; in fact its relative freedom from unpleasant or serious side-effects is

¹ *Deutsch. med. Wochs.*, 1939, 65, 567.

² *Quart. J. Pharm. Pharmacol.*, 1940, 13, 318.

³ *Arch. intern. Med.*, 1943, 71, 545.

claimed as an advantage over morphine. A more serious drawback is that the duration of action is not as long. Battermann and Mulholland⁴ have reported in greater detail on the effectiveness of the drug in the control of post-operative pain and restlessness, and conclude that for such cases demerol is actually more suitable than morphine. The advantages that they claim are its antispasmodic effect on the gastro-intestinal tract, its atropine-like drying action on mucous membrane, its lack of suppression of the cough reflex, and the rareness with which respiratory depression follows its use.

The important question of liability to addiction to demerol after its use over considerable periods of time has been studied by various observers, and the evidence suggests that physical dependence on and abuse of the drug can occur. In Battermann's series no instances of real dependence were detected, although a few of the patients expressed a desire for the drug, possibly because of its analgesic and sedative action or because of the euphoria occasionally induced; none of these patients, however, experienced any withdrawal symptoms. This is a question calling for further study, and indeed the claim to have produced a synthetic drug which can rival morphine in its analgesic potency and safety is one which on many accounts requires extensive, careful, and critical assessment before demerol can be regarded as a suitable substitute for the opiates in the relief of pain.

HYPOGLYCAEMIA AND NEUROTIC BEHAVIOUR

Within recent years there has been notable shift of interest from the psychological study of abnormal mental states to the humoral or biochemical aspect. This viewpoint has been given prominence by the work of Gjessing on schizophrenia and that of Jahn and Greving on the so-called "asthenic constitution." Of all such studies, however, those of the relation between hypoglycaemia and behaviour have attracted the widest attention and have yielded startling results. It is necessary for the psychiatrist and neurologist faced with the interpretation of, perhaps, even a common syndrome to be aware of a possible hypoglycaemic basis, and never to overlook it.

A number of papers have appeared in recent years on the clinical neuropsychiatric aspects of hypoglycaemia, and two have recently been published, the first by Rennie and Howard⁵ and the second by Romano and Coon.⁶ The latter is a comprehensive, carefully written study of a single case—

of a man aged 44, an emotionally rigid, sensitive, dependent person with much latent aggression, who exhibited recurrent episodes of confusion, dyskinetic movements, and uninhibited emotional behaviour. The initial diagnosis was of a hysterical fugue state. Further observation revealed that these phenomena were associated with hypoglycaemia due to a benign islet-cell adenoma of the pancreas. After removal of the tumour these episodes ceased, though the personality of the patient remained unchanged. This study is of value, as it correlates with precision the biochemical, neurological, and psychological disturbances. The other two authors describe a series of cases of so-called "tension depression," where the individual's disability was primarily his psychiatric condition in which the abnormal mental state was associated with hypoglycaemia. They consider that the latter is a disturbance which derives from a variety of possible factors, and they stress the fact that one of these is that of the total individual. They believe that the hypoglycaemia in their series was secondary to the psychiatric disorder, since it appeared with treatment of the psychiatric condition.

Whether this inference is justified is open to doubt; the facts are capable of alternative explanation. Be that as it may, the authors succeed in demonstrating the importance of the hypoglycaemic factor, particularly in such illnesses as they describe, and the need for keeping alive to the possibility of this relationship. Both papers show that there need be no correlation between the level of the blood sugar and the abnormal behaviour. Thus in Romano and Coon's patient there was no physiological or psychological disturbance of any degree on one occasion when the blood-sugar level was only 31 mg. per 100 c.cm. of blood. They add that this lack of correlation does not exclude the possibility that glucose may be mobilized and utilized without this being reflected in the blood-sugar values, and, further, that technical errors in the chemical assay of glucose at these levels may be considerable. Rennie and Howard point out that the usual blood-sugar norm should be interpreted with latitude; that there are wide variations in the blood-sugar level outside the accepted range of the norm which may produce little or no discomfort. The fasting level is inadequate for the determination of hypoglycaemia—a statement with which everybody with experience of this problem will agree. This was shown in several of the cases of Rennie and Howard, in which the hypoglycaemia only appeared after 4 hours' observation of a glucose-tolerance test. They noted that the relative degree of decline during the test (rather than arbitrary limits) may be more important in bringing about symptoms. Romano and Coon make again the frequently recorded observation that rapid reduction of glucose level produced disturbances in consciousness and neurological phenomena. They believe that the data so far obtained point to diminished oxygenation in the brain, probably as the result of diminished oxygen uptake. They give due weight to modern methods of psychological testing, and demonstrate the reversible impairment of intellectual function which occurs during the hypoglycaemia characterized *inter alia* by the more "concrete" type of behaviour in the sense of Goldstein.

OPHTHALMIC RESEARCH

A pamphlet entitled *Eyesight and National Health* and printed by the University Press outlines a plan for the foundation of a Department of Ophthalmology at Oxford for research, teaching, and treatment. It is sponsored by a strong body named the University of Oxford Ophthalmological Research Endowment Committee, and the cost of the appeal is being met by the National Institute for the Blind. The University appeals for funds towards the following objects: (a) the provision and equipment of laboratories, lecture rooms, a library, and a museum in connexion with the Oxford Eye Hospital, the rebuilding of which will be begun at the end of the war; (b) the provision of salaries for full-time and part-time research workers and teachers engaged in the new department; and (c) the defraying of working costs of researches which would have for their aim prevention of blindness, improved treatment of eye disease, and promotion of a higher standard of visual function throughout the country. The pamphlet sets out some facts about eyesight in general, and gives an indication of the results already achieved for the betterment of vision and of lines on which future research will proceed. The new research centre at Oxford is intended to be flexible and collaborative. The sum aimed at is £250,000 for building, equipment, and endowment. We shall have more to say about this admirable project and its implications.

We much regret to announce the sudden death in Aberdeen of Surgeon Rear-Admiral Sir William Courcy Wheeler.

THE PUBLIC CORPORATION

BY

D. HARCOURT KITCHIN

Barrister-at-Law

It has been proposed that soon after the war the Government shall set up a new system of social insurance, the benefits of which shall include every variety of medical attention. If this were done, machinery would have to be established by which every insured person might be given with certainty and smoothness the medical service he needed. The Government has suggested that the medical practitioners working the scheme should be organized into a salaried State service and controlled by the medical officers of the local authorities, but this idea at once aroused widespread and determined opposition. As an alternative, some members of the profession are in favour of the establishment of a "public corporation" to administer the medical side of the social insurance scheme. The arguments in favour of this solution have been ably set out in the Interim General Report of the anonymous body, Medical Planning Research.¹

The purpose of this article is to survey the structure and functions of some of the public corporations in this country in a search for data which might help in the design of a new corporation to administer nation-wide health services. I have been greatly assisted by the thesis² of the eminent American economist, Dr. Lincoln Gordon. Unless some other source is indicated, quotations come from that work, but readers will also gain much help from the work of Dr. W. H. Robson³ and Dr. J. D. Millett.⁴

With the expansion of the country's industry, many public utility services—ports, transport, electricity, and the like—have had to be removed from individual enterprise to some form of public control. This control has often been municipal, but the usefulness of a local authority is limited to its own area and resources. It is also unduly susceptible to local political influences. On the other hand, a few public services have been administered by a central Department of State—e.g., the Post Office, Public Works, and Crown Lands. The chief objection to this arrangement lies in the shortcomings of "bureaucracy." A civil service department may be an adequate regulator of private enterprise, but it is a bad organ of positive administration. Its decisions can be made only by the men at the top, its finances are rigidly controlled by the Treasury, and it is subjected to constant political attack. It is, therefore, inevitably slow, timid, and unenterprising. Such efficiency as the Post Office has is due to the reforms of the last decade, which made its administration in some degree independent. The practice has therefore grown up of placing public services which call for creative activity and initiative—when they become too large and important to leave to individual enterprise or local authorities—under the control of bodies created *ad hoc*, designed on the model of a joint-stock company but without its profit-making incentive.

Origin and Organization

The public corporation, board, or concern, as it has been variously termed, is not peculiar to this country, but has taken here a form especially suited to our national mentality and requirements. It embodies the admirable principle that the best way to get a given job done is to appoint capable and responsible people to do it and leave them as free as possible. It is usually placed under the control of a Minister, who is responsible for it to Parliament, but he does not, nor does Parliament expect him to, interfere with its day-to-day conduct. He indicates from time to time the general policy that the Government wish it to follow, and sees that its finances are duly administered. In the way in which it appoints its staff and does its work it has almost complete autonomy within the terms of the statute or charter which created it. It may be publicly criticized in Parliament and outside, but it reacts to this criticism according to the judgment of its members. Parliament and the Minister have the ultimate power to control it, but, realizing that its value lies in its freedom, they leave

that power unused. Its organization is not hierarchical, like that of a State Department, but parallel, like that of a commercial concern. Its staff perform services, tackle problems, and take decisions according to the needs of the actual situation and without much regard to general principles or theories.

In practice, the public corporation has been outstandingly successful. It has been distinguished by initiative, enterprise, efficiency, and financial stability.

"It has . . . combined most of the advantages of State ownership with those of commercial administration. If it has not always precisely found, it has at least indicated, the location of that delicate equilibrium point between administrative freedom and public responsibility which is the fulcrum of efficient public enterprise so controlled as always to act in the public interest."

The motive of successful and creative public service has proved to be quite as dynamic as the motive of profit-making. This is not surprising, for much of the initiative and efficiency that are said to characterize private enterprise as opposed to official administration is provided by salaried workers who gain nothing material from the success of their concern.

The modern British public corporation is evolved from the autonomous local port trust. This is usually elected by ship-owners and merchants using the port and paying its dues and rates, and derives its revenue from charges on shipping and goods. It is, as Gordon points out, a public authority predominantly representative of its immediate consumers, who form a relatively compact and unchanging group. The port trust itself developed out of municipal control, and its most imposing modern descendants are the Port of London Authority, the Mersey Docks and Harbour Board, and the Clyde Navigation Trust. By no means all public corporations, however, share the representative character of these bodies. A public corporation can in practice only be representative if it serves "a geographically compact and well-organized body of direct consumers whose principal common interest accords with the most desirable general policy for the undertaking." The Metropolitan Water Board is representative, but its unwieldy governing body is designed to stress "the idea of public representation and public responsibility" (Departmental Committee on Metropolitan Water Act, 1902, Cmd. 845, 1920) rather than to secure commercial efficiency. Such a corporation exists only because no single local authority has jurisdiction over the whole area. It is slow-moving, prone to sectional conflicts, and has, in Mr. Herbert Morrison's words, "a great deal of joint and not enough authority." (House of Commons Official Report, March 23, 1931; vol. 250, col. 54.) Where the public corporation has to serve a large area and its consumers are not organized, it is far better designed as a small non-representative board appointed by a Minister.

The medical profession itself contains a clear-cut example of the representative public board in the General Medical Council. The G.M.C. would probably be considered by the majority of those members of the profession (not a numerous class) who know anything about it to fulfil its functions adequately. On the rare occasions when it is required to act in accordance with a specific policy of the Executive (as in shortening the curriculum to meet the wartime need for more doctors), the close contact between its President and the permanent officials of the Privy Council makes co-operation swift and certain. Few of its critics complain that it does not maintain a high enough standard of competence in recruits to the profession. It has been attacked for the high average age of its members, which has been placed at 67 years: if this is a handicap it could only be remedied by altering the present system of representation. The Council's contact with the licensing bodies seems to leave nothing to be desired. Its duties do not call for a very intimate contact between it and the profession at large.

The Board of Control, which supervises the management of mental defectives and persons of unsound mind, is another public board with a good deal of autonomy, and is ultimately responsible to the Minister of Health.

London's Water Supply

At the beginning of the century London's water supply came from a large number of independent undertakings, municipal and private. The inconveniences of this situation were so great that Parliament in the Metropolitan Water Act, 1902, created

¹ *Lancet*, 1942, 2, Special Supplement.² *The Public Corporation in Great Britain*, Oxford, 1938.³ *Public Enterprise*, G. Allen and Unwin, 1937.⁴ *The Unemployment Assistance Board*, G. Allen and Unwin, 1940.

and incorporated the Metropolitan Water Board to "purchase, manage, and carry on the undertakings of the existing companies and to supply water within the area." Like the G.M.C., this board is an elected body, its members being chosen by the London County Council (14), the cities of London and Westminster; the Metropolitan Boroughs, the Essex County Council, the Conservators of the Thames and Lee, and the other local authorities concerned. Like many bodies of the kind, one of its first duties was to acquire a large number of going commercial concerns. The undertaking of each of the Metropolitan water companies was transferred to the new Board and vested in it, compensation being fixed by agreement or arbitration, and paid (if so agreed) wholly or partly in water stock. The agreement, to be valid, had to be unanimous and confirmed by the Court of Arbitration which also was created by the Act and which could modify an agreement. As in all such Acts, full provision was made for the transfer of staff from the expropriated undertakings to the Board, and for their rights on superannuation, on the lines already laid down for Metropolitan authorities.

Political responsibility for the Metropolitan Water Board was laid upon the Local Government Board, and in 1919 passed to the new Ministry of Health. The Minister has power to alter the representation and the total number of members of the Board to meet variations in the population of the local authority areas supplied by it, and to include new urban districts. He may hold local inquiries at his discretion to investigate complaints and representations. The M.W.B. makes an annual report and statement of accounts to the Minister.

Port of London Authority

Another typical representative public corporation is the Port of London Authority, which was set up by the Port of London Act, 1908, to administer, preserve, and improve the Port of London, actually to bring order into a chaos which threatened to drive most of London's trade out of the country. The Authority took over the undertakings of the three existing dock companies in the port, all the functions of the Thames Conservators below Teddington, its landward limit, and all the powers of registering, licensing, control, etc., which had previously been vested in the two associations of watermen and lightermen. It was given power to acquire land and to borrow, and its revenues come from rates on goods passing through the port, a maximum yearly total being fixed. It is now governed by the Port of London (Consolidation) Act, 1920—a private Act. It chooses its own chairman and vice-chairman, who need not be members, and they may receive a salary. They are elected for three years and are eligible for re-election. Seventeen of its members are elected by the ratepayers, wharfingers, and owners of the river craft in the port, and one by the wharfingers.

The keeping of the register of voters is one of the Authority's ties, and the elections, like all the work of the Authority, supervised by the Ministry of Transport. These members serve for three years and may be re-elected. In addition, members are appointed by the Admiralty, the Ministry of Transport, the L.C.C., the City of London, and Trinity House. The Ministry and the L.C.C. must each appoint one of their members after consulting organizations representative of labour. In practice, as Gordon shows, there is no real general representation even within the broad categories. The labour representation, though apparently unsuccessful in the early days, has borne fruit as the labour members have widened their interest from the single matter of the welfare of the workpeople to include the larger problems of administration.

Legally the Port of London Authority is subject to potential control by Parliament and to more immediate control by the Board of Trade and the Ministry of Transport. Its powers and their limits are set out in minute detail in the 1920 Act, but in practice it is far more independent than it appears on paper. The Minister of Transport speaks for it in Parliament, but its doings cannot be debated on his vote, as it is financially autonomous. Members have not discussed it on the adjournment nor on a private member's motion. Its day-to-day operations are not subject to debate. In 1912 (*Official Report*, July 22, vol. 41, col. 816) a private member claimed to move to consider its alleged failure to relieve traffic congestion and "decasualize" labour, but the Speaker ruled the motion out

of order: the Board of Trade, he said, has no controlling power through its representatives on the Authority, even if it gives them instructions, and cannot compel the independent Authority to take a particular line. Ministers have since disavowed control, and said that their appointees are not delegates who act under instructions. Complaints are referred back to the Authority, and the Minister has not even general power to require it to fulfil its statutory obligations. Either the Board of Trade or the Ministry has revisory jurisdiction over nearly all the Authority's administrative functions, and limiting powers over its commercial functions. These restrictions, however, are hardly ever used, and the Minister never withholds approval unless to safeguard other interests. Ministerial action is usually quite nominal.

Similarly, the P.L.A. is immune from direct political influence. In its labour disputes, which have been many, it declines to allow the Government to interfere. "Such outside control as exists is designed merely to offset the character of the Authority as a miscellany of interests." Control is most stringent, and the Authority's independence is most liable to encroachment in the sphere of finance. The chief executive officer of the Authority is the general manager, but the Board closely supervises all non-routine matters of administration, and determines even minor questions of policy.

Forestry

The Forestry Commission is historically the first example of the non-representative public board. It was set up after the last war by the Forestry Act, 1919, to repair the damage caused by the wholesale and largely indiscriminate cutting of the country's timber. State-owned woodlands and the ancient Crown forests were transferred to the Commissioners, and the leased some plantable land from the Commissioners of Crown Lands. They executed schemes of afforestation and supervise forest workers' holdings. Briefly, their work, which they have done energetically and well in spite of many disturbances and checks due to changes in Government policy, is "to grow timber and encourage others to do the same." The Commission was originally not a corporation, but it was incorporated as an afterthought to facilitate its purchase of property.

Unlike most bodies of this kind the Commission is not supervised by a Minister. There are ten commissioners, appointed for five years each by the Crown, nominated by the Prime Minister in consultation with the Agricultural Departments. One is appointed chairman, one must be a Member of Parliament, two must have special technical attainments; not more than three may be paid. By practice, not law, each of the three chief political parties has a representative. Executive work is done by an assistant commissioner each for England and Wales and for Scotland appointed by the Commissioners. Consultative committees sit for England, Wales, and Scotland. Committees are appointed to deal respectively with personnel, estates and holdings, technical matters, and national forest parks. The Commission itself deals with policy, finance, personnel, research, education, and publications.

The Commission, though very much of a law unto itself, is subject in various ways to the control and scrutiny of Parliament. Its mouthpiece is its parliamentary commissioner, who presents its annual estimates for approval; and on this occasion its policy and actions are open for discussion. Its accounts are examined by the Comptroller and Auditor-General, and every year the Public Accounts Committee summons and questions its accounting officer. The parliamentary commissioner answers routine questions, and occasional questions on policy are answered by the Prime Minister or the Chancellor of the Exchequer. By the 1919 Act it is subject to full Treasury control, and in acquiring land it is obliged to consult with the Agricultural Departments.

Though the Commission is, on paper, an independent body, it is actually more like a small Government Department than a public board of the modern kind. Its exercise of its executive powers is subject to Treasury direction, and the appointment and remuneration of its staff to Treasury approval. Its accounts are State-audited, and any surplus in the Forestry Fund is managed by the Treasury. State control over it is, therefore, unusually extensive. Gordon explains this status by a reminder

5 Post-War Forest Policy. Report by H.M. Forestry Commissioners, Cmd. 6447, 1943, H.M. Stationery Office. (2s.)

that, broadly speaking, its policy is primarily political rather than commercial. Trees are strategically important; moreover, they take a very long time to grow. The Commission can never be self-supporting, but must draw most of its revenue from the State, which is, therefore, bound to supervise it correspondingly closely. More than that, its revenue fluctuates with variations in Government policy. Nevertheless, as a small body appointed by Ministers and combining expert, commercial, and general qualifications, it stands on the direct line of descent of the present public corporations from the port trusts.

[To be continued]

SAVING THE VOLUNTARY HOSPITALS

Surveys in North-East England

The latest report of the North-Eastern Regional Hospitals Advisory Council, representing eleven local authorities and thirty-five voluntary hospitals in Northumberland and Durham, states that at the council's request the Ministry of Health and the Nuffield Trustees have appointed two officers to make a survey of hospitals in the region. The officers appointed were Prof. J. A. Ryle (until his recent appointment at Oxford, when he was succeeded by Sir Hugh Lett) and Dr. A. E. Quine of the Ministry. All the hospitals in Newcastle, Sunderland, Middlesbrough, and the Hartlepoons have been visited and meetings have taken place with the hospital authorities in each area. A survey of pathological services has been made by Dr. Wells, and proposals for the joint operation of the three public health laboratories in the Newcastle area are being considered by the local authorities concerned and by King's College, Newcastle. The council also took the initiative in summoning a conference of local authorities and the larger voluntary hospitals to consider the establishment of a co-ordinated service for the diagnosis and treatment of cancer. The Lord Mayor of Newcastle undertook to prepare a scheme which has now been considered in detail by two further conferences. The financial position of Durham County Hospital has greatly improved with the launching of the hospital contributory scheme, the initial cost of which was met by the council, and the income from this source in 1942 amounted to £14,800. The first instalment of the Nuffield grant, amounting to £2,000, was paid to the hospital last year, and payment of the second instalment is now recommended.

Merseyside.

Last year the Merseyside Hospitals Council distributed £155,758 to the associated voluntary hospitals, £31,714 to the medical staffs fund, £14,928 to other voluntary medical institutions, £38,790 as payment for treatment in municipal hospitals, and £21,953 to civic war charities. Employees' contributions amounted to £272,585, and employers' contributions to £60,973. Owing largely to the penny-in-the-pound fund, the voluntary hospitals have doubled their income since the fund started. In order to bring the income limit for free medical treatment in the open wards of the voluntary hospitals into line with National Health Insurance, it has been arranged, with the good will and consent of the Hospitals Medical Staffs Association, to increase that limit to £420 per annum for all non-manual workers (for manual workers there is no income limit). Liverpool Corporation has entered into a new agreement with the council concerning payments for maintenance of contributors and their dependants admitted to municipal hospitals.

TREATMENT OF TUBERCULOSIS IN WALES

On Aug. 20 a deputation from the Welsh National Memorial Association, headed by Lord Davies, met the Minister of Health, Mr. Ernest Brown, to impress upon him the need for more accommodation for the treatment of tuberculosis in Wales. The deputation stated that in spite of the fact that the Ministry of Health had made available 200 beds in emergency hospitals, the association's waiting list for institutional treatment had now passed the 500 mark. Moreover, patients had had to be discharged from sanatoria before completing their course of treatment. The association therefore asked that more casualty beds should be set aside for tuberculous patients; or, if this was impracticable, a temporary sanatorium should be built in South Wales. The Minister, in reply, said that it would be possible to restore to the tuberculosis service 50 casualty beds at the Morriston Hospital, Swansea, and to make available a 30-bed block in Monmouthshire. Other possibilities of providing additional beds would be explored. The main difficulty, however, was one of staff. The Ministry of Labour was now carrying out a campaign to recruit sanatorium staff, and he hoped that soon there would be an increase in the supply of nurses and domestic staff which would relieve this pressing problem in both Wales and England.

Correspondence

Foundations of a Comprehensive Medical Service

SIR,—Permit me to comment on the most interesting letter by Dr. George F. Buchan (Aug. 28, p. 278). I will take the three foundations he presents seriatim.

1. "A Health Ministry to include all the health functions of Government Departments and with health its sole function." There will, I feel sure, be general agreement that this reform should be carried out, and the sooner the better. There is, however, one all-important matter not touched on by Dr. Buchan—admittedly he, by reason of his position in the Public Health Service, could not discuss it—namely, the constitution of the "directing body" at the Ministry of Health. At present this body includes: (a) the Minister of Health and his secretaries, (b) a staff of medical officers of health, (c) an advisory committee. Many of us are not satisfied with an "advisory committee"; we desire to see an executive body set up—in other words a "Health Council," on which would be representatives from all bodies actively engaged in medical practice in its many forms (general practice, special practice, research, nursing, etc.), and from other bodies which should naturally be represented on a Health Council. A great principle is involved in this proposal, which has been put forward from time to time by individual members of the medical profession long interested in the creation of a comprehensive medical service. The purpose is to bring those who are more especially concerned with administration into closer relationship with those more directly engaged in medical practice and research. They contend that this reform would be of benefit to both parties and make for greater efficiency in the service. Naturally the Health Council would have to be of considerable size. Special boards or committees would deal with particular problems—e.g., obstetrics would have its board or committee. The parent council and its boards or committees would be relieved of much detail by committees of the large Government areas, which is the second foundation referred to by Dr. Buchan.

2. "That local government areas of sufficient size and with adequate resources be established, in each of which the administration of a comprehensive health service could be satisfactorily carried on." Obviously this is a most desirable reform. That it will meet with opposition from many of the smaller local authorities is to be expected.

3. "That following upon 1 and 2 powers should be given to the new local government authorities to plan and develop such a comprehensive service as might be considered best for their respective areas after consultation with the local medical profession. In coming to this conclusion the society [the Society of Medical Officers of Health], while supporting a whole-time salaried service, nevertheless realized that all reasonable methods of medical practice should be tried out before any final conclusion can be reached." This appears a reasonable proposal, but my contention is that, as with the central authority so with the local authority, it is not sufficient to have a policy determined "after consultation with the local medical profession." The medical profession should have representatives on the "health boards" of local authorities, additional to the medical officers of health who *de facto* are members of these boards. This is a matter of the very greatest importance, as otherwise the advice of medical officers of health, avowedly in favour of a whole-time salaried service (as Dr. Buchan admits), will determine the policy of the health boards of local authorities. Indeed it is probable that in some areas "part-time service" might not get a fair deal—to put it quite crudely but none the less truthfully—unless the medical profession of the area have a selected number of its members on the health boards of the area.

This brings me to the question of a part-time and whole-time service. On this Dr. Buchan states rather naively: "I am unaware that any responsible body advocates the immediate adoption of a whole-time salaried service." But why not put it in the positive form, always so much stronger than the negative: "That a number of responsible bodies have made definite pronouncements against a whole-time salaried service."

The course of events in recent months has been rather interesting—a general veering off from a whole-time salaried service. At the moment the hot-headed and plausible revolutionaries (there are always these two types in a revolutionary party) have been halted; while the younger members of the profession, who were at first rather carried away by the idea of a whole-time salaried service because of the security it promised, are, on second thoughts, a little doubtful if the best comprehensive medical service for the community can be secured by so simple a device as a whole-time salaried service. All countries, including Great Britain, have certain of their medical services whole-time and salaried. But in how many are the services rendered by general practitioners and specialists whole-time and salaried? Sweden, which is often quoted as an illustration of a really well organized and educated democracy, has not a whole-time service for all practitioners.

In the course of time, should a part-time service prove disappointing and inadequate a whole-time service will have to be introduced. But a very large number of the medical profession contend that it is possible to organize a part-time service which will prove satisfactory in every respect, and will preserve the intimate relationship between doctor and patient which has been a feature of medical practice in this country, and indeed in many other countries. Nothing must be done to sacrifice that great tradition. We resent extremely the attempt made by partisans of a whole-time service to rush their policy through. All we demand is that a fair trial be given to a well-organized part-time service. In other words, that we proceed with reforms in the medical services of the country in the traditional British manner.—I am, etc.,

Canterbury.

JOHN M. MUNRO KERR.

Conditions for Effective Health Service

SIR.—The object of State service, most are agreed, is to supply a method of administration which will remove inequalities that cause widespread hardships, especially among the less affluent. These inequalities are mainly concerned with provision of our basic necessities—health, food, housing, fair play, law. Can a State medical service function effectively and fairly—i.e., can it provide the greatest benefit for the greatest number, lay and medical—while the callings responsible for the other basic needs are run on the opposite principle of individual competition and devil take the hindmost? It is doubtful. As their interests are so interdependent, would not the efficiency-ruining effects of mixing opposing principles of administration soon be apparent? The first condition of effectiveness would therefore be like administration—i.e., State service—for basic needs.

Many of us were glad, therefore, that the B.M.A. decided to withhold support for State service; we felt it would be a pity to see such a great humane idea exposed to discredit by launching it into practice in circumstances adverse to success and to the majority of the profession and public had fully considered its implications. Which brings me to the second condition.

Namely, discussion, much more discussion, between both medical and lay, especially the rank and file of the various callings, before final decision. The subject is too large and intricate for any one individual to be didactic, and too important to all, both medical and lay, for individual apathy.

Medicine and law offer probably the most useful illustration of the interdependence and need for similar administration. Two of the main human necessities, without which life is savourless, are health and fair play or justice. The means or procedure for procuring them, reason suggests, should not, therefore, be for sale or exploitable. Since mental health is necessary for physical, is not a satisfied sense of fair play the basic requirement for a nation's health of mind and contentment? From this emerges a fundamental principle and policy of health planning—namely, the best available medical and legal skill must be at the disposal of all on equal terms independent of purse. There is evidence that not only doctors but many lawyers, also sociologists, lay and clerical, are thinking so.

If this view is reasonable then medical plans are but part of a greater nation-wide one, and must be made to fit the latter like pieces in a puzzle. We should all, especially our planners, keep the design as a whole in mind. Indeed the world generally, signs daily indicate, is at last realizing that, for providing

our basic necessities, co-operation must supplant individual competition if health, fair play, and human needs are to be equitably satisfied for all. Our individual competitive urges can find outlet in less injurious ways. It would be unwise to regard this as revolutionary; is it not rather a very relevant example of that slow and more desirable method of change—evolution? Nor is it Utopia; it is common sense and decency, and is probably the good, the great and only good, which the ill wind of war is angrily blowing to our perception.—I am, etc.,

London, S.W.3.

P. K. MURPHY.

Freedom or State Control?

SIR.—One aspect of the present controversy about the future of our profession has not been brought to notice. It is a most important and fundamental point.

The 19th-century individualism has been discredited and the pendulum has swung across towards the demand for State control of life in all details. Parallel with this inevitable reaction in thought there is the demand for freedom. The correlation of these two demands has presented through the ages, and still presents, the greatest theoretical and practical difficulties. Let it not be forgotten, therefore, that during the last hundred years freedom for the individual has been won by groups and unions of trades and professions working within the Constitution for the welfare of its members, who play a double role both as citizens and as engineers, miners, doctors, teachers, and lawyers.

The present demand for a State Medical Service, which would place our profession under the direct control of the "lay public," is made more vociferously by those who would be least willing to give up their hard-earned freedom as members of a craft or trade union.—I am, etc.,

Wimbledon.

R. D. FOX.

Views of Doctors in the Services

SIR.—Now that the medical departments of the three Services have given permission for medical officers on active service to meet and discuss the future of medical practice (*vide B.M.J.*, Nov. 28, 1942) it is to be hoped that more letters from this large and important section of the profession will appear in the medical press. Hitherto any representation of their views has not been greatly in evidence.

I recently acted as chairman at a meeting of medical officers from the three Services stationed in the North of Scotland, and it is their wish that our resolutions should appear in the correspondence columns of the *Journal*. It is with their full approval that I forward this letter.

First, we wish to call the attention of our colleagues on active service to the urgent need for them to express their opinions on the vital matters which are now under consideration.

We unanimously agree with the decision of the Representative Committee to request the withdrawal of the proposals for a State service under the Minister of Health and local government boards. It is our opinion that the Government, in planning for the future health of the nation, should consider first things first. For example, as it is generally agreed that the living conditions of a large portion of the community are responsible for much ill-health, the housing problem would appear to be a more urgent matter than the reorganization of the medical profession.

We further consider that, when new propositions are placed before the profession, a questionnaire should be sent to all practitioners on active service whom it is possible to reach, and that no decision should be made until they have had time to express their views.—I am, etc.,

H. L. HOFFMAN,
Surgeon, C.M.D., R.N.V.R.

Improving Hospital Administration

SIR.—I am anxious to call attention to some matters of hospital administration which, to my mind, urgently need alteration if the main function of these institutions—namely, the complete restoration to health of their patients—is to be in the fullest sense attained.

(1) *Hours at which Patients are Awakened.*—This in many hospitals is far too early. Patients are roused by the nursing staff for the purpose of washing, etc., as early as 4 a.m. This is a harm-

ful procedure because it disturbs the sleep of sick people and starts their day, often very long and monotonous, before they are really ready for it. It not only makes their stay in hospital more irksome, but actually hinders their convalescence by interference with a very essential part of their treatment—plenty of undisturbed sleep. This very early waking is not necessary. It is carried out mainly in order to get the wards ready for the visits of doctors. Any efficient matron, with the good will of the medical and nursing staffs, can remedy this matter with little trouble. It is merely a matter of rearrangement of work. No patient should be waked earlier than 6.30 a.m. in summer or 7 a.m. in winter.

(2) *Visiting Days.*—A happy contented mind is a valuable help to rapid convalescence, and, as those of us who have been in hospital or nursing homes know, a powerful contributory factor to this state is the visit of friends or relatives, so much looked forward to by patients. Instead of the usual twice-a-week visiting day, every day should be one in which patients can receive their friends. Again nothing but a little rearrangement of hospital routine is necessary. Many hospitals have already made such concessions and have thereby earned the lasting gratitude of patients and their relatives.

(3) *Time of Waiting for Out-patient Treatment.*—Under the present system all patients, no matter how many there may be, are summoned to the out-patient department at the same time. It is a common sight to see thirty, forty, or more crowded into a room, many not even able to obtain a seat, all waiting their turn to be seen. It may be three or even as much as six hours before the last is seen. This long weary period can be got rid of by the system of out-patient appointments. It is already in operation in many hospitals with conspicuous success. The waiting period has been reduced from hours to minutes. Punctuality of attendance by the physicians and surgeons is, of course, essential. The appointment system should be part of the routine of every hospital.

(4) *Waiting Lists of Patients for Admission.*—In many hospitals there is a long list of patients waiting admission mainly for operative treatment. In one hospital the chief surgeon recently told me the list was often over one thousand. In one of our local hospitals a patient was told in July that she needed operative treatment, and that her name would be put on the list and would probably be reached by December. This is all wrong. It is very hard on patients to have this long period of anxiety. It is actually harmful and in many cases militates against the chance of cure. It is largely due to the want of beds which obtains, especially in this time of war. But it can be overcome. Other hospitals are willing to co-operate. The one with no waiting list will help those with overcrowded lists. As an example, recently a local hospital found itself with about 60 patients urgently needing treatment. With the willing and friendly assistance of a neighbouring hospital, the list was completely cleared in less than a fortnight. I know hospitals and surgeons do not like parting with their patients, and that patients do not like parting with their doctor, but the good of the sick person should come before everything. This vitally important reform—the prevention of these long lists of patients needing admission—is overdue and should be attacked seriously by all hospitals.

(5) *Rehabilitation.*—This is an old word, but I am using it in a new sense—the complete restoration to bodily and mental health of any patient treated for accident, illness, or disease. Too often the hospital, for want of facilities, is compelled to stop short of this ideal. The surgeon performs his operation brilliantly and successfully. The convalescence of the patient, whether at home or in the hospital, is a dreary wait filled with anxiety for the future. Will he ever get really fit and be able to resume his former occupation and earn his former wages? This anxiety neurosis keeps him back and too often drives him into chronic neurasthenia, invalidism, and inability to return to normal life. The remedy is a proper system of rehabilitation. By this I mean not only physiotherapy (massage, exercises, radiant heat, ultra-violet rays, etc.) but such things as occupational therapy—either remedial or diversionary—outdoor games such as cycling, swimming, and team games, and useful work such as gardening, wood-sawing, or log-splitting, all under control, with proper instructors and supervisors, and so arranged with periods of rest that the whole day of the convalescent is usefully and enjoyably occupied. Thus the patient is interested, trained, and reassured, and his return to his usual life and to useful citizenship settled and hastened. This is no impracticable ideal. Rehabilitation centres are rapidly being established and doing wonderful work. The Royal Sussex County Hospital has in operation one of these centres under the aegis of a keen and competent physician and a keen and competent sister, and is doing good work. It is making arrangements at the present time to increase and improve rehabilitation facilities and is an example of which Sussex may well be proud. Complete restoration to fitness is one of the most important parts of medical treatment. It has been, and is, too much neglected. The Ministry of Health is taking up the matter very keenly, and in the near future every hospital must have its rehabilitation department, or, if too small to be able to have its own, should arrange for facilities at a larger centre if it is to

function properly. By this means we shall be getting so much nearer the real essence of treatment—the complete return to positive health of every patient.

—I am, etc.,

Hove.

L. A. PARRY.

Aetiology of the Fibrositic Nodule

SIR,—Lieut.-Col. Copeman's suggestion (Aug. 28, p. 263) that influenza may be the underlying cause of "rheumatic nodules" and "myalgic spots" is very interesting. He quotes as exciting causes of pain and local tenderness: cold in the head, mumps, sandfly fever, glandular, undulant, and scarlet fevers, measles, and rubella. All of these share with influenza one common feature—fever.

Many individuals have rheumatic nodules of whose existence they are unaware until they become painful; when they do so examination will disclose other nodules which have not yet become painful. If such an individual is treated by artificial fever—e.g., by the pyretic bath—an almost constant experience is that the tender areas become for a short time more tender and many of the hitherto painless nodules also become tender. This appears to be a direct result of raising the body temperature. May it not be true that the role of influenza is merely to act as a similar excitant of a condition which is already present though unsuspected because it has not yet called attention to its existence by causing pain?—I am, etc.,

London, W.1.

C. E. SUNDELL.

Childhood Infection and Adolescent and Adult Phthisis

SIR,—Dr. Macpherson in the *Journal* of July 24 (p. 98) has shown that a 0.43% increased incidence of cases of pulmonary tuberculosis in young adults has been revealed by recent mass radiography. She states that according to the hypothesis in Report V these symptomless adolescents are the very people who eventually will develop manifest disease, and that in the majority of these cases the expected spread of the disease comes sooner or later after a variable interval. She has not stated how many of these symptomless young adults develop active disease, but we know that many of the adult population are infected as revealed by tuberculin tests and yet get no active disease, and that secondary healed lesions are found frequently at post-mortems. It may be argued that their tuberculin-sensitiveness is due to healed primary lesions.

Finally, it is suggested that the majority of these young adults without symptoms, physical signs, or fever, with normal gain in weight and normal blood sedimentation rate, should have immediate treatment by artificial pneumothorax. The few exceptions are those who can afford the time for prolonged home rest. I venture to suggest that this is perhaps rather too sweeping a proposal. After many years' continuous practical experience in artificial pneumothorax I feel that it should not be lightly undertaken in any individual. Each case should be judged on its merits. There is always the danger that once the pleural surfaces have been separated by an air space in any individual, that individual is exposed to one of the greatest risks in pulmonary tuberculosis—namely, the possibility of a spontaneous pneumothorax into an A.P. space, with its frequent consequences, effusion, empyema, and often death, unless, as sometimes happens, the pleural infection is arrested by various drastic methods. Possibly with expanding modern thoracic surgery the fear of this risk is less, but I do not know if that is so. One criterion before starting an A.P. should be, 'Is the disease more dangerous to the patient than the A.P. or vice versa?' Some of these symptomless adults come under the latter category. One cannot guarantee that a shallow pneumothorax will not give rise to serious complications. A shallow bilateral pneumothorax may be as easily tolerated as a unilateral one, but it doubles the risks of complications. I question whether such widespread action should follow from a mere hypothesis.

Even in symptomless cases pulmonary tuberculosis is now regarded as a local manifestation of a general disease. A.P. does not cure the latter, but assists the general defences, and is merely a local splint. It is equally important to treat the general condition, which A.P. patients, feeling secure, are apt to neglect despite supervision at refills. I think it is often a mistake to allow A.P. patients to return to work or school soon after A.P. is started, owing to risks of outside infection.

I think the proposal that the large majority of these symptomless young adult cases of pulmonary tuberculosis discovered by mass radiography require there and then to have an A.P. done should not be accepted without due consideration. If this proposal is accepted there may be many regrets in individual cases.—I am, etc.,

Edinburgh.

A. NIVEN ROBERTSON.

Tuberculosis in Childhood

SIR,—In your leader on tuberculosis in childhood reference is made to a report by a subcommittee of the British Paediatric Association. As I have not had the privilege of receiving a copy I was much interested in your leader. The recommendation that there should be some mechanism whereby children suffering from erythema nodosum or phlyctenular conjunctivitis can be brought to the notice of the tuberculosis officer surely presents no difficulties. Here in Sheffield, where the school medical service works in close liaison with the tuberculosis dispensary, every child suffering from either of the defects mentioned above is referred to the tuberculosis officer. I mention this point advisedly as it is stated the document "forms a serious indictment," and it might appear that the school medical service had not realized the need for the further examination of these children.—I am, etc.,

H. M. COHEN.

School Medical Officer.

Sheffield.

SIR,—In your leader on tuberculosis in childhood (Aug. 28, p. 270) you mention a report by the subcommittee of the British Paediatric Association. This has not yet been published, and in the form in which I saw it over a month ago it contained some recommendations—e.g., "special clinics, staffed by those with paediatric experience"—which would not, I think, be accepted by the majority of tuberculosis workers. Divorce of the discovery and follow-up of child contacts from the main tuberculosis scheme would certainly be a controversial suggestion. However, the B.P.A. has been so sensible as to consult with the bodies more directly concerned with tuberculosis, and I hope that the report when it gets the wider publicity which you desire will show some modifications.—I am, etc.,

High Wood Hospital for Children, Brentwood.

J. V. HURFORD.

** We understand that the report of the British Paediatric Association is soon to be published in full.—Ed., B.M.J.

Preventive Medicine through Breast-feeding

SIR,—Our profession of late has had a great deal to say about "positive health" and the part the practitioner should play in "preventive medicine." So distinguished a layman as Sir William Beveridge has echoed the expressions, with evident endorsement. Yet the first is undefined and the second, as used, misleading. "The prevention . . . of disease . . . by medical treatment" and "diagnosis of disease in early stages when it can be prevented" are seen to be statements of the impossible when thoughtfully considered. When first the patient ("sufferer") comes to the doctor and skilful earlyagnosis discovers the disease from which he is suffering, it is too late to "prevent" it. Prevention is a different sort of thing altogether. "Prevent us, O Lord, in all our doings with Thy most gracious favour" should be our right line of thought; and the G.P., through the nutritional advice he gives, can do something to guide some of his clients into the same. Those clients will be the mothers of present and future children. Food, its own wholesomeness and quality, is the chief factor in health. What the mothers eat forms the children. Contrast the teeth of Asiatics, breast-fed in infancy, with those of our people, and then consider the advice we give in the child welfare centres. "Lactogen doesn't suit: better try 'Cow and Gate.'" The advertisements of the patent "nutrients" adorn the walls. That is the "atmosphere" to which we invite the so-called nursing mother.

It is our own profession who bear the main and ultimate responsibility for the vital blunder of the "civilized" mammal of our genus—mammal in name but not in function. In the last war Sir Truby King was brought from New Zealand to show our people the error of their ways. He brushed aside the plaintive "I can't feed him," "My milk went when I got up," withered with his scorn the pleaders of "social duty" as an excuse for bottle-feeding, taught women whose lactation

was poor how to feed and manage themselves, reinforced the old true teaching of the Rotunda Hospital about the prevention of breast induration—would that our schools would teach it and the result of his efforts was that women who "couldn't feed their babies did, and found themselves proud to do so.

Yesterday one of us had occasion carefully to examine hundred or so children for a baby show. Seen one by one thus in a chain the links of precious metal, "the breast-fed" were recognizable: vital good-skinned, not heavier—often so heavy. One vividly recalled Truby King's story of the "bucket-fed" boots: the "Paris calf" was from the R. veal—that is, from the calf that had been suckled by the cow not so the cheaper boots—the "bucket-feds."

Do our colleagues who conduct welfare centres have such thoughts in mind? Do they recall the Chicago figures? A total of 20,061 infants attending the centre between 1924 and 1939 were closely followed for the first 9 months; 9,749 (48.5%) were wholly breast-fed, 8,605 (43%) partially, and 1,707 (8.5%) artificially fed upon a definite plan. All were attended at intervals by centre officials. Of the breast-fed 15 or 0.15% died, of the "partially" 59 or 0.7%, while of the artificial fed 144 or 8.4% died, 82 of them from respiratory infection. Will not the fifty-six times greater mortality of the artificial fed at last modify the practice of our so-called "welfare centres"?—We are, etc.,

OLIVER BLACKLAW.

LIONEL JAS. PICTON.

JOHN R. T. TURNER.

Views on Diabetes

SIR,—For some months a controversial correspondence on the treatment of diabetes mellitus has appeared in your column. To those who are accustomed to the control of this malady several points of interest arise which offer scope for investigation by physiological workers.

The blood sugar is placed on too high a level to the exclusion of other factors. It is a condition which is easily altered from day to day by worry, overwork, tobacco, and alcohol. When a patient attends a clinic all that can be known about his blood sugars is their state on one particular day when the patient arrives in a prepared state and his curve behaves like a description in a textbook. Of his habits, diet, and blood sugars for the previous three months nothing can be assumed. Because the blood-sugar percentage is regarded by many as a reliable index of the severity of the condition, all the complications such as cataract and retinitis are attributed to a raised blood sugar. Why should we not assume that these are due to a deficiency of insulin and not to a raised blood sugar?

What is the mechanism of the control of hypoglycaemia? Is it to be considered that the blood sugar is raised merely by the digestion of a carbohydrate food?—It is true that the symptoms are relieved by a carbohydrate drink or lump of sugar, but the alleviation is often so rapid (30 to 60 seconds for considerable amelioration) of symptoms is not unusual that it appears unreasonable to believe that the digestion of the carbohydrate is the only factor responsible for the rise of the blood sugar. I venture to suggest that mechanical stimulation of the gastric mucosa may play an important part.

For a number of years I have felt that the present method of the control of diabetes is based on an incorrect principle of regarding the blood sugar as the only guide in treatment. I am of the opinion that it is the insulin content of the blood which should decide the line of treatment, and, until such a time when we shall possess knowledge of the normal blood insulin, its variations, and a simple biochemical method of its assessment, we shall always rest in stagnated pond with its minor periodical waves of dissension.

I shall not enter the field of pentosuria and ask why excess of glucose in the blood is thought to lead to cataract, while excess of arabinose or xylose leaves the lenses unchanged, but it is pitiful to note that in spite of the great deal of correspondence on diabetes with the exception of a more liberal diet (and even this not by all physicians) and the development of a multiplicity of insulin compounds, the understanding of the principles of diabetes and the method of treatment have undergone very slight alteration in the last 20 years.—I am, etc.,

Edwards.

A. D. MATTHEWS.

Peripheral Arterial Embolism

SIR,—Having read Major H. Agar's article (July 24, p. 101) I am prompted to record this case of peripheral arterial embolism and successful embolectomy.

A man aged 32 was admitted to the casualty department at Ancoats Hospital about 12.30 p.m. on July 5, 1943, complaining

of severe pain in the right groin and loss of sensation in the right leg, which apparently had started quite suddenly about 8.30 a.m.—i.e., 4 hours previously—while he was setting out to work. Clinical examination revealed absence of pulsation in the dorsalis pedis, posterior tibial, and femoral arteries on the right leg, which was cold and pale. There was anaesthesia to pin-prick from toes to knee. Aortic pulsation could be felt in the abdomen. The heart, though not enlarged, showed a Stage II mitral stenosis with regular rhythm. A diagnosis of arterial embolism at the bifurcation of the common iliac artery was made and the patient admitted. He was operated on within the next hour by the resident surgical officer, Mr. I. J. Philp, who successfully removed an embolus (patient under spinal anaesthesia) which was sitting on the bifurcation of the right common iliac, with a large tongue passing into the external iliac and a very small tongue into the internal iliac. The patient recovered from the operation, has normal circulation in the leg, and was apparently quite fit when seen a few days ago—six weeks after operation.

There are three interesting features in this case. First, successful embolectomy was performed seven hours after occlusion of the vessel. Secondly, the vessels containing the clot were in spasm although a spinal anaesthetic had been given. Thirdly, the patient had mitral stenosis with regular rhythm. Subsequent x-ray examination of the chest showed no enlarged left auricle where the thrombus could have been formed, but in view of Sir Maurice Cassidy's statement that these cases are usually due to active endocarditis it will be interesting to see if the man develops any sign of the disease or any further emboli.

Finally, I would like to stress, as does Mr. Guthkelch (Aug 21, p. 245), the importance of early diagnosis, and the more widespread realization by general practitioners in particular that early operation can be successful.—I am, etc.,

B. WOLMAN,
Resident Medical Officer.

Anceats Hospital, Manchester.

Precision Method of Cephalometry and Pelvimetry

SIR.—Dr. Millington's criticisms (Sept. 11, p. 338) of the radiometrical method described by me in the *Journal of Aug. 1* (p. 196) may be summarized under three headings: (1) The method compares unfavourably with those usually employed in depth location examinations. (2) In pelvimetry the method may give as good results as others but it requires heavy exposures. (3) In cephalometry it is inaccurate, since the two shadows are cast by completely different diameters of the object. My answers to the above objections are as follows:

1. The method is designed primarily for measurement of certain diameters and is not intended to replace the well-established methods of depth location.

2. Its chief use in pelvimetry is for measurement of the transverse diameters of the inlet and outlet. I have proved by practical experiment on a dried pelvis that (in my hands) the method is more accurate than the Thoms grid method for reasons which I have already stated. It is of equal accuracy to the horizontal stereoscopic methods of Hastings and of Dippel and Delfs (U.S.A.), and its results are less affected by inadvertent errors in the tube-shifts. Moreover, it allows the calculation to be done in one stage instead of in two. I shall say more about its theoretical accuracy in the paragraph on cephalometry. In regard to exposures, there is not the slightest reason why they should be abnormally high. Accurate results are obtained with 40-in. and 30-in. tube-film distances, and as the examination can be made with the patient in the supine position the method is within the capacity of most medium-powered sets. Average exposures at these distances, using fast screens and films, are 250 and 200 milliampere-seconds at 70 kV. Distances longer than 40 in. and 30 in. are unnecessary, although they improve bone detail if adequate power is available.

3. In regard to cephalometry, I am indebted to Dr. Millington for pointing out a theoretical error as it has prompted me to calculate the error and to prove that it is negligible. Dr. Millington's diagram is, of course, not intended to be in proportion, and it makes it appear that the two false diameters are much above the true diameter. Reconstruct the diagram to correspond with normal working conditions—i.e., with the tube 40 in. and 30 in. above the film and the foetal head a circle of

4 in. diameter with its centre point 7 in. above the film—then it is at once apparent that the false diameters are very close to the true diameter. (Confirmatory evidence for this statement is given by Holmquest (*Radiology*, 1938, 31, 198), who states that "for anode-film distances employed in roentgenography the error in dimension is negligible.") In actual fact their calculated distances are 0.12 in. and 0.18 in. respectively above the diameter. The lengths of the shadows of these two diameters on the film are 4.85 in. and 5.2 in. respectively. Applying the formula, we have this sum:

$$\frac{5.2 \times 4.85 \times 10}{(5.2 \times 40) - (4.85 \times 30)} = \frac{252}{62.5} = 4.03 \text{ in.}$$

Thus the theoretical error is +0.03 in. No gynaecologist would quarrel with an error of this order. In fact, to all intents and purposes the result is dead accurate.

The above figures can be checked by calculation or graphically. Similarly, one can calculate the error in the final result supposing that the tube-film distances have been measured inaccurately. If, for instance, a careless radiographer took the films at 43 in. and 33 in., and the radiologist worked on the routine basis of 40 and 30 in., in his calculation the result would be 3.96 in. instead of 4 in., an error of only 0.04 in. Or take another example: when the tube is wrongly placed at 40 in. and 33 in., the result is 4.23 in., an error of +0.23 in. When it is realized that a similar mistake of 3 in. in setting up a horizontal tube-shift would have disastrous effects on the final result the comparative immunity to abuse of the vertical tube-shift method is striking.

Dippel and Delfs, in their excellent article on the subject in *Surgery, Gynecology and Obstetrics* (May, 1941, 72, 915), make the definite statement that "errors in tube-film distance do not produce as great technical errors as do errors in total tube-shift distance." They refer in the above sentence to lateral tube-shifts. I must therefore strongly repudiate Dr. Millington's contention that the method is liable to serious errors. On the contrary, theoretical considerations have confirmed my practical experience that it is rightly termed a method of precision. Whether or not this method of cephalometry and pelvimetry is "new" I cannot say. I have never seen any reference to it in the literature. The idea of using a vertical tube-shift was taken, as I have already indicated, from work published by Portés and Blanche in 1924, but my method differs in many respects from theirs.—I am, etc.,

Reading.

PAUL CAVE.

"The Classics"

SIR.—Dr. Clark-Kennedy has given us food for thought in his paper published on Sept. 4. For him the classics primarily mean the Greek writings, an opinion any medical scholar must incline to hold. No writer whose mother-tongue was Latin made a first-rate contribution to our science or to any other branch of science. Indeed the contribution of Rome to general literature was, in comparison with that of Greece, small. But the direct influence of, say, Virgil, Horace, and Cicero upon the thought and style of our modern predecessors has been far greater than that of their masters. There is the further point that power to read Latin is a key to the whole of medical literature down to the 19th century. Without that key, much professional literature of the 15th to 18th century is closed to us.

It is, I suggest, for educational experts to decide whether it is possible to equip young people with a reading knowledge of Latin by means of a less laborious drill than veterans remember. If it is possible, then, in my view, Latin ought to be a compulsory subject of medical pre-education. I have sometimes wondered whether the choice of authors for reading in schools is judicious. At 63 I often read Virgil, Martial seldom. At 16 Martial would have given me more pleasure than I was capable of deriving from Virgil. At the M.R.C.P. examination I was required to construe this epigram:

Languebam; sed tu comitatus protinus ad me
Venisti centum, Symmache, discipulis
Centum me tegere manus aequilone gelatae;
Non habui febrem, Symmache, nunc habeo.

The point is not very sharp but might bring home to the young that these terrible people, as Dr. Blimber's pupils not unreasonably regarded them, the Romans were natural human beings, not actors in costume plays.—I am, etc.,

MAJOR GREENWOOD.

Obituary

A. W. BYRNE, C.B.E., M.B.

An obituary notice of Dr. Austin William Byrne, expert adviser in public health to the Egyptian Government, who died on July 10, appeared in the *Journal* of Aug. 7. We are now able to print extracts from a personal appreciation written by Dr. A. Cecil Alport, F.R.C.P., professor of clinical medicine and director of the Medical Unit at Cairo University.

The death of Dr. Austin Byrne came as a shock to his many friends in Egypt. After a distinguished academic career Dr. Byrne joined the Regular R.A.M.C. and went to India, where he held various responsible posts during the last war. For his services he was mentioned in dispatches and received from the Government of India a special letter of thanks and a special souvenir. Throughout the whole of India he was well known as a sportsman and one of the best gentlemen riders in the East. He was invalided from the Army in 1919, and in 1925 was appointed as expert adviser in public health and tropical medicine to the Government of Egypt. In this post, as in all appointments he held, Austin Byrne proved to be an unqualified success. His charm of manner, his sympathetic nature, and his unfailing courtesy made him

extremely popular not only in English but also in Egyptian Government circles: he was, in fact, exactly the type of man that England requires in a position such as he held in Egypt. In August, 1941, he was appointed by the Council of Ministers to the important post of president of the International Quarantine Board and technical adviser to the Quarantine Administration of Egypt. Dr. Byrne was due to retire in 1940, but duty kept him in Egypt, and in the end he literally worked himself to death. At the outbreak of war, apart from his other duties, he became chairman of the committee which organized the groundwork of all medical arrangements for air-raid precautions in Cairo. In addition, he had in 1939 become liaison officer between the Egyptian Government Medical Services and the British and Allied Forces in Egypt. Austin Byrne's life was a full one. He died in harness, and his passing leaves a gap in the circle of his friends, both British and Egyptian, which it will be difficult to fill.

WILLIAM PASTEUR, C.B., C.M.G., M.D., F.R.C.P.

The consulting staff of the Middlesex Hospital has lost another member through the death on Sept. 1 of Dr. William Pasteur at the age of 87. He died at Tunbridge Wells, where he had made his home since retiring from active work. He was the fifth in seniority on the roll of living Fellows of the Royal College of Physicians of London.

William Pasteur was educated privately at Maidenhead and then at University College, London, and qualified in 1880 from the M.B., where he became house-physician. He took the M.D. in 1882, and proceeded M.D. in 1884, after post-graduate study in Vienna clinics. Settling in London he was elected assistant physician to the Middlesex Hospital and to the Queen's Hospital for Children in Bethnal Green; he was for many years a member of the visiting staff of both institutions, and eventually consulting physician. For nearly the whole period of the last war Dr. Pasteur served, with the temporary rank of colonel, A.M.S., as consultant physician to the British Armies in France, succeeding his senior Middlesex colleague, Sir James Kingston Fowler, at the Rouen base. For his military services he was mentioned in dispatches and created C.B. and C.M.G. He joined the British Medical Association in 1894, was a corresponding member of the Belgian Royal Society of Public Medicine, and a past-president of the Medical Society of London. He had been examiner in medicine for the Universities of London, Durham, and Birmingham, and for the English Conjoint Board during two periods. He was elected F.R.C.P. in 1891, served on the Council of the College in 1909-11, and was censor in 1915-16; he gave the Bradshaw Lecture at the College in 1908. His presidential

address to the Medical Society of London was on post-operative lung complications. Thoracic disease had long interested him, and the war of 1914-18 gave him a wide field for study of gunshot wounds of the chest, which for the first year were mainly left by the surgeons to the care of the physicians at base hospitals.

A man of inborn dignity, with a straightforward and kindly manner which reflected his true nature, Dr. William Pasteur was looked up to by all. Here, one felt, is a physician who will give his whole mind to the case and treat it with wisdom and understanding. Such clinical teachers leave the mark of their personality on a receptive student when he passes into practice.

We regret to announce the death at Gloucester, on Aug. 28, after five weeks' illness, of Dr. JOHN WILLIAM HUNT, who had won the trust and affectionate esteem of his many patients as a fellow practitioners during his ten years' work in that city a his long term of office abroad. He was educated at Oxford and then became a medical student at St. Mary's Hospital, London, qualifying M.R.C.S., L.R.C.P. in 1900 and passing his final examination for M.B. at the University of London the same year. He served for a time at the Hendon Sanatorium, after which he joined the Colonial Medical Service holding the position of house-physician at the Royal Somers Hospital, Capetown, and later of district medical officer in Fiji, where he lived for 23 years. Then he returned to England and served twice as hon. secretary of the local Branch of the B.M.A., and worked devotedly in his Gloucester practice, where his never-failing good humour, kindness, and ready sympathy gained for him staunch friends, who deeply mourn his loss. He is survived by his wife and daughter.

Universities and Colleges

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on Sept. 6, the President, Mr. James H. MacDonald, in the chair, the following were admitted Fellows of Faculty *qua* physician: C. B. Ainscow, M.B., Ch.B. A. K. Boyle, M.D., J. Manhas, M.R.C.S., V. T. Smith, M.I.C. W. Maclay, F.R.C.S., was admitted a Fellow of Faculty *qua* surgeon.

The Services

Two officers of the Indian Army Medical Corps figure among the recipients of awards for gallantry in North Africa. Capt. N. A. Subramaniam, M.B., medical officer of a battalion of the 9th Gurkha Rifles, was awarded the M.C. for outstanding bravery and devotion to duty during the Djebel Garci Hills operations in April. He not only skillfully dressed under shellfire the wound of those brought to the regimental aid post, but repeatedly moved out into the shell swept zone to attend to the casualties of his own and other units which lay there. Capt. C. Arumainayagam, attached 2nd Gurkha Rifles, was also awarded the M.C. During the operations in April in the Enfidaville sector, although on more than one occasion knocked down by blast from bursting shells, he continually moved about over a wide shell-swept area tending the wounded. "Knowledge of his presence," states the citation, "had a definite effect on the morale of the battalion."

Surg. Lieut.-Cmdr. (Acting Surg. Cmdr.) J. O. Clyde, R.N.V.R. has been awarded the R.N.V.R. Officers' Decoration.

CASUALTIES IN THE MEDICAL SERVICES

Died on Active Service.—Fl. Lieut. J. M. Barkla, M.B. F.R.C.S.Ed., R.A.F.V.R., youngest son of Dr. C. G. Barkla, F.R.S. Professor of Natural Philosophy, University of Edinburgh.

Prisoners of War.—War Subs. Capt. A. Barber, R.A.M.C., Temp. Lieut.-Col. H. C. Benson, R.A.M.C., Temp. Major P. B. Hanbury, R.A.M.C., Acting Major N. C. Lendon, R.A.M.C., Capt. J. S. McConnachie, R.A.M.C., War Subs. Capt. K. C. Matheson, R.A.M.C.

Previously Missing, now officially presumed Lost at Sea.—Capt. E. J. A. Needham, R.A.M.C.

No. 34

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital statistics in the British Isles during the week ended August 28.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) the 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales increases were recorded during the week in the incidence of scarlet fever 374, diphtheria 87, and ophthalmia neonatorum 40, while notifications of whooping-cough fell by 100, dysentery by 69, and measles by 63.

The rise in the number of cases of ophthalmia neonatorum was due to an increase of 43 in Birmingham C.B. The increase in scarlet fever was general, the highest figures being for London 84 and Lancashire 50. Notifications of diphtheria were higher than for the past three months, especially in Lancashire 33 and Glamorganshire 25. The fall in the number of cases of whooping-cough was mainly confined to the North; in the South there was a slight increase, the only local variation of note being a decline in Yorks West Riding of 55. Notifications of measles fell below 1,000 for the first time for 14 years. While there were 63 fewer cases of measles in Kent, an outbreak was reported from Lincolnshire, East Elloe R.D., where notifications rose from 2 to 66.

The lower incidence of dysentery was mainly due to a decline from 57 to 13 cases in Yorks West Riding. The other centres of infection were London, Kent, and Lancashire, with 19, 13, and 11 cases respectively.

In Scotland notifications of diphtheria rose by 53, and scarlet fever (continuing a general rise) by 68. The increase in whooping-cough, 25, occurred in the Western area. Dysentery was still prevalent, the largest returns being from the cities of Glasgow 24, and Edinburgh 14.

In Eire the only region from which any cases of measles were reported was Dublin C.B. Three-quarters of the notifications of whooping-cough were recorded in two areas—Dublin C.B. 15, and Sligo R.D. 19. The apparent large increase in cases of infantile diarrhoea and enteritis was due to the inclusion in a Dublin hospital of 210 cases which occurred during the past three months.

The Week Ending September 4

The returns of infectious diseases in England and Wales during the week included: scarlet fever 2,206, whooping-cough 1,928, diphtheria 625, measles 674, acute pneumonia 304, cerebrospinal fever 43, dysentery 238, paratyphoid 14, typhoid 11.

Influenza in South Africa

During August there was an epidemic of gastric influenza in Johannesburg, chiefly among children. At one period 40% of the pupils at some of the city schools were absent.

Medical News

The annual general meeting of the Marie Curie Hospital will be held on Thursday, Sept. 23, at 3 p.m. at the Rembrandt Hotel, Thurlow Place, S.W.

The autumn programme of the Royal Sanitary Institute includes meetings in Rhyl, Leamington, London, and Bath. On Saturday, Sept. 25, at 10.30 a.m. in the Town Hall, Rhyl, Dr. A. E. Roberts will read a paper on the Government milk policy, and Mr. M. Emlyn Thomas on milk administration. On Saturday, Oct. 16, at 10.30 a.m. in the Town Hall, Leamington, papers will be read on town and country planning and on sampling under the Food and Drugs Adulteration Acts. On Wednesday, Oct. 20, at 2.30 p.m. at the Royal Sanitary Institute (20, Buckingham Palace Road, London, S.W.1) there will be a discussion on the problem of sewage disposal in rural areas. On Saturday, Nov. 6, at 10.15 a.m. in the Pump Room, Bath, papers will be read on food standards and on housing.

The London Area Committee of the Association of Scientific Workers is holding a conference at the Essex Hall, Essex Street, Strand, W.C., on Saturday, Oct. 2, at 2.30 p.m. for the purpose of surveying and discussing the many questions of medical and nutritional relief, and examining the technical measures that must be taken to deal with them. The speakers will include Prof. J. R. Marrack, Mr. F. Le Gros Clark, and Mr. Aleck Bourne.

The London School of Hygiene and Tropical Medicine has arranged a week-end course for medical practitioners on Factory Medical Services and Industrial Diseases on Saturday and Sunday, Oct. 2 and 3, at 2 p.m. The fee for the course is one guinea, and applications should be made to the Secretary of the School, at Keppel Street, Gower Street, W.C., not later than Monday, Sept. 27.

* Includes primary fever for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

This year Hospitals Day in the London area will be held on Tuesday, Oct. 5. Offers of service should be sent to the London Hospitals Street Committee, 36, Kingsway, W.C.2.

The annual general meeting of the Association of Industrial Medical Officers will be held at 11 a.m. on Saturday, Oct. 16, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C. In the afternoon a paper will be read by Dr. M. W. Goldblatt on the investigation of toxic hazards.

The September number of the *Practitioner* opens with five articles which form a symposium on medical sociology. The first is by Sir Farquhar Buzzard, writing on social medicine and the general practitioner; the second is by Sir Arthur MacNalty, on public health and the future; the third by Prof. J. M. Mackintosh of Glasgow, on housing and health (in the form of three candid letters to a doctor); the fourth by Dr. J. A. Charles, on instruments of social medicine outside the hospital; and the fifth by Miss Margaret Roxburgh, on the work of a hospital almoner.

On June 1 Major-Gen. Norman T. Kirk became Surgeon-General of the United States Army in succession to Major-Gen. James C. Magee, who has retired.

Dr. Hermann Louis Kretschmer, a well-known urologist of Chicago, has been elected president of the American Medical Association.

News has been received from Prof. D. E. C. Mekié, F.R.C.S.Ed., of the Singapore Medical School, and from Major W. J. E. Phillips, R.A.M.C., that they are safe and prisoners of war in Japanese hands. Dr. L. John Clapham, Colonial Medical Service, is reported a prisoner in Borneo.

The Royal Medical Foundation of Epsom College announces the following vacant pensions. In November next the Conjoint Committee will make an award of £35 per annum to a spinster daughter of a medical man; candidates must be Protestants and fully 65 years of age. The Council of Epsom College will, in December next, award a "France" Pension of at least £30 per annum to a necessitous medical man, fully 55 years of age, who has been registered for five years. Forms of application for these pensions may be had from the Secretary's Office, Epsom College, Surrey, and must be completed and returned by the morning of Oct. 25.

The Minister of Health and the Secretary of State for Scotland received last week a deputation from the National Conference of Friendly Societies, accompanied by representatives of the Scottish Association of Friendly and Approved Societies, the National Conference of Industrial Assurance Approved Societies, and the Joint Committee of Approved Societies. The deputation put forward the case for the retention of approved societies in any social security scheme and made suggestions on the part they might most appropriately play. The Ministers undertook to give full consideration to the deputation's views.

Special classes in the use of exercise in the post-war rehabilitation of children in occupied countries are being conducted by the Ling Physical Education Association for the International Women's Service Groups (headquarters, 1, Cambridge Place, W.1). These classes are part of a course in pioneer training for relief work abroad. They are based on the principles laid down in the pamphlet noticed in the *Journal* of Aug. 7 (p. 170).

Letters, Notes, and Answers

communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, Ailology Westcent, London; SECRETARY, Mediscera Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Puerperal Exercises

Q.—What particular forms of exercises should a woman perform both early and late in the puerperium, in order to make a quick recovery to normal? What other forms of rehabilitation are advisable in the puerperium?

A.—On the second day after delivery the mother should be instructed in deep breathing as well as foot exercises. With the patient

lying flat on the bed without a pillow, the legs should be crossed firm adduction and all the pelvic floor muscles contracted stern. She should now turn the trunk to the right and at the same time stretch the left arm over to the right side of the bed. The trunk and arm movement is now reversed. By this means the pectoral (thus increasing circulation to the breasts), abdominal, and pelvic floor muscles are all brought into action. Perineal stitches do not preclude this exercise provided it is performed evenly and suddenly contractions are avoided. During the afternoon rest the prone position the mother should be reminded to practise pelvic floor contractions. Late in the puerperium a valuable exercise to stand against a wall with the arms well above the head, and an upward stretch of the arms a general contraction of all muscles is performed. This can also be done hanging from a bar or top of a door, and helps to correct postural defects. If exercises are practised assiduously special forms of rehabilitation are unnecessary. The ideal is for exercises during the puerperium to be supervised by a trained masseuse. Equally important are exercises (the practice of relaxation) during the ante-natal period.

Cough Medicine in Phthisis

Q.—Phthisis patients often ask for "a bottle of medicine for cough." Is there any danger that expectorants such as iodides may aggravate the tuberculosis?

A.—No, there is no danger that expectorants such as iodides might aggravate the tuberculosis. It was at one time thought that iodides broke down fibrous tissue in tuberculous foci and liberated tubercle bacilli into the sputum. Hence their administration for the purpose of diagnosis to suspected cases of pulmonary tuberculosis in which tubercle bacilli had not been found in the sputum. This view is not now accepted, the effect of the iodide being to loosen the mucus and aid in its expectoration. When phthisis patients ask for a bottle of medicine for the cough, however, it is not always wise to prescribe one. The dry, ineffective cough of pulmonary tuberculosis can be largely checked by the patient's own effort.

Bacteraemia after Tooth Extraction

Q.—I understand that patients with mitral stenosis and other anatomical defects of the heart are sometimes given sulphonamides prophylactically in order to minimize the danger of bacterial endocarditis after tooth extraction. I am likely to have a bacteraemia after an impending extraction, and would like to know of a suitable sulphonamide, its dosage, and length of course.

A.—Both sulphydrydine and sulphathiazole are known from their effect in endocarditis lenta to have an action on *Str. viridans* which although subject to variation with the strain of organism, should be adequate for prophylaxis: the latter drug is to be preferred because on account of its apparently greater activity and because its selective toxic effects are less. The bacteraemia after dental extraction is believed to be very transient, but owing to the prolonged exposure which is necessary to secure the sulphonamide effect, bacteria, medication should presumably be continued well beyond this short period. Doses of 2 and 1 g. given 4 and 2 hours respectively before extraction should secure an adequate initial blood concentration, and 1 g. administered four-hourly for a further 48 hours will maintain it for what is probably a sufficient length of time. In the absence of apical infection, the source of the bacteraemia is saliva or other material sucked into the tooth socket by the vacuum created. Another useful precaution is therefore to dry the surrounding gum thoroughly with spirit before extraction or, if pyorrhoea is present, to cauterize it.

Peptic Ulcer Pain

Q.—Has the pain of gastric ulcer been successfully treated by the use of local anaesthetics, administered by mouth?

A.—Local anaesthetics, such as benzocaine gr. 5 in a cachet have been administered by mouth for the treatment of gastric ulcer. The method is unlikely to prove successful, and is not recommended. The pain of gastric ulcer usually responds rapidly to the orthodox method of treatment by rest in bed, milky feeds, antispasmodic and neutralizing agents. If the pain persists despite adequate treatment, it indicates that the condition is more serious. The ulcer may be large, penetrating, and adherent to adjacent structures, requiring surgical treatment. Or it may be malignant.

Inheritance of Epilepsy

Q.—As there seems to be some diversity of opinion about the hereditary nature of epilepsy, could you let me know what is the present teaching on the subject? Is it advisable for an epileptic to marry and have children?

A.—Although many conditions which are not inherited may simulate it, true epilepsy is hereditary. This is proved by many pedigrees and by the fact that in the case of uniovular twins both or neither are affected. It appears to be a very incomplete dominant, and the likelihood that a given epileptic will have epileptic

children must be judged by a study of the family tree. It is probable that some will be genetically epileptic, even if they never have fits, and will transmit the condition to some of their descendants. On eugenic grounds, therefore, it is wiser for an epileptic not to have children.

Menstrual Migraine

Q.—Can you give me any advice on methods of alleviating the incapacitating "blinding" headaches suffered by a woman of 43 or about 24 hours at the start of practically every period? She is not neurotic, and at ordinary times leads a strenuous life, but when her headache is bad she simply cannot do anything. A subtotal hysterectomy for fibroids some years back has made no difference, and, so far, any treatment has failed to make her fit to run her household one day a month.

A.—If the patient is still menstruating, it is to be assumed that only a small portion of the uterus was removed at subtotal hysterectomy, and that at least one ovary was conserved. The case is one of so-called "menstrual migraine," which is thought to be due either to increased sensitivity to anterior pituitary hormone or swelling of the pituitary gland, or changes in the intracranial blood supply associated with the hormone cycle. The most severe form of these headaches occurs when the roof of the pituitary fossa is calcified, when it is presumed that enlargement of the gland is restricted. The pituitary fossa should therefore be x-rayed.

If the headache is of pituitary origin, a large dose of oestrogens (e.g., stilboestrol 1 mg. t.d.s.) should be given for two or three days premenstrually, in the hope of inhibiting the pituitary. The dose and timing may have to be varied, and the difficulty is that a dose sufficient to depress pituitary activity sometimes defers the onset of menstruation. Alternatively, try ergotamine tartrate with a view to reducing intracranial congestion. But many cases are intractable, and as a last resort deep x-ray therapy to the pituitary should be considered—particularly when the roof of the sella turcica is calcified. However, it is fraught with real risk, especially of producing side-effects such as obesity, and this should be explained to the patient beforehand.

The D Vitamins

Q.—I am slightly bewildered by references in the literature to various D vitamins, numbered 1, 2, 3, etc. Do these differ in their action on the human being, and is there any superiority in the natural vitamin over that artificially produced? I should also be glad to know the modern view on the physiological action of vitamin D if it can be given within the short compass of an answer.

A.—There are at least ten substances with a vitamin D—i.e., antirachitic—activity. For practical clinical purposes only two—D₁ and D₂—are of any importance. D₁, or calciferol, is a synthetic substance obtained by exposing ergosterol to ultra-violet irradiation. D₂ is the naturally occurring vitamin present in animal fats and fish oils, and formed on the human skin by solar radiation on 7-dehydro-cholesterol in the sebium.

So far clinical studies have been made on vitamins D₁ and D₂, only. There is complete disagreement on their relative values. Some authorities state that the antirachitic value of the two vitamins is the same; others deny this. Provided that more than the minimal dose is being taken it probably does not matter whether D₁ or D₂ is given. It must be remembered, however, that if vitamin D is given in the form of cod-liver oil, the latter also contains vitamin A, valuable fats, and iodine. Vitamin D₁ is never extracted commercially. The only commercial vitamin is D₂.

The fundamental action of vitamin D is to regulate the metabolism of calcium and phosphorus, the absorption and mobilization of which are under its control. In the absence of sufficient vitamin D, absorption of Ca and P is inadequate, excessive quantities are lost in the faeces, and the serum calcium and phosphate fall. This leads to incomplete ossification of developing bone, which becomes soft and rarefied, as seen in rickets. Ossification of developing bone is normally started by the deposition of calcium phosphate in the cartilage. It is probable that vitamin D also stimulates growth *per se* and exerts some effect on muscular and intestinal tone. There is no convincing evidence that lack of vitamin D is a factor in dental decay in human beings.

The Seborrhoeic State

Q.—Have there been any recent advances in the treatment of the seborrhoeic state, leading as it seems to do to hyperkeratosis, acne, or dermatitis, and hairfall? The local and general treatment as given in the textbooks is well known, but is there any more specific method of inhibiting the sebaceous overaction and thus getting at the cause of these complaints? Is x-ray treatment of value?

A.—There have been no striking advances in the treatment of the seborrhoeic patient, who appears to have a background of predisposing factors—inherited, nervous, endocrine, and metabolic—which constitute the so-called seborrhoeic diathesis. When some of these aspects, discussed in any modern textbook, are adequately

dealt with, good progress may result, but the most experienced dermatologist will fail to influence some of his seborrhoeic patients who exhibit an uncontrollable susceptibility to infections of their skin and mucous membranes. Seborrhoea is not an invariable clinical feature of the seborrhoeic patient, for in some cases the patients have dry, scaly skins and no evidence of overaction of their sebaceous follicles. X-ray treatment is of value, but it would be dangerous to employ it in dosages sufficient to inhibit permanently the glands of the skin.

INCOME TAX

House Furnished but Uninhabited

F. C.'s house has been uninhabited since January, 1941. He left the town until October, 1941, when he returned, but "for private and domestic reasons has since then been living in a hotel." The house is furnished and kept in reserve as an emergency surgery. F. C. is paying one-half the local rates. He was not taxed under Schedule A for two years, but has now received a demand note for "tax for the current year."

** (Tax for the current financial year is not due until Jan. 1, 1944; the demand would therefore seem likely to be for the year to April 5, 1943.) It would seem that our correspondent is not prevented—e.g., by Defence Regulations or because of authorized requests to leave the town—from making full use of the house, and as it is furnished and available for his occupation we do not know of any grounds on which he can claim relief from the tax charged.

Error in Notice of Assessment

R. W. explains that through an arithmetical error in the income-tax office the notice of assessment which he received showed the amount of tax payable as £119 15s. 9d. instead of £219 15s. 9d. His employer was similarly misinformed, so that only £59 17s. 10d. was deducted in the first half-year, and £159 17s. 10d. is now claimed in the second half-year. Can he object to the increased payment? Information is also asked for as to the amount of the personal allowance given.

** The error was clearly a bad one, but, we gather, could have been detected by R. W. by examination of the figures in the notice. In any event, however, the fact that the error was made and led to insufficient deductions in the early months of the year does not prevent the revenue authorities from arranging for collection by deduction of the full amount of the true liability. With regard to the personal allowance, R. W.'s marriage increases the amount from £80 (the single man's allowance) to £140—i.e., by £60, the tax on which, at 10s. in the £, is £30—the figure quoted to him by the income-tax office.

Inclusion of Book Debts

E. G. started practice in July, 1942. Is he liable to include unpaid book debts in calculating his profits?

** Yes. The "cash basis" is not legally correct, but is accepted as giving a sufficiently approximate result when a practice has been running for some years. In the first two or three years the full earnings are below those shown by the net cash takings. E. G. should, however, bear two points in mind. First, that it is the value of the debts which should be brought into the calculation—i.e., a deduction from the full amount can be made for an estimate of the probable loss through non-payment. Secondly, that if the inclusion of the uncollected debts makes payment of the resulting tax too serious a hardship, the collector will no doubt allow part of the tax to be paid by later instalments.

Purchase of Book Debts

G. M. has recently purchased a further share in a partnership paying £400 for outstanding book debts. Can he claim any income-tax relief in respect of this sum?

** No; the payment represents capital laid out in the purchase of further assets and cannot be regarded as an allowable deduction for income-tax purposes.

LETTERS, NOTES, ETC.

London Paste

Dr. IRWIN MOORE (London) writes in criticism of the answer given to a question about London paste under "Any Questions?" (July 31, p. 158) as follows: As solely responsible for unearthing, in a paper read before the Summer Congress of the Section of Laryngology, Royal Society of Medicine, in May, 1919, this very valuable and efficient remedy from the overlooked literature of the past and, after improvements in technique, replacing it in its proper and scientific position, I can only express my great surprise at the adverse opinion expressed by your commentator, and I accept his remarks as a direct challenge to my advocacy of this treatment, which after a life experience of the guillotine and dissection method

of surgical removal of the tonsils I can without any hesitation recommend as the most satisfactory and efficient substitute. The statement that Morell Mackenzie "does not appear [to have] attempted to destroy the tonsils with it, or [even to have] recommended [its use]" is not confirmed by the facts, for he published in 1864, in the *Medical Mirror*, his experience of 40 cases in which he had successfully used it in his private practice, and he stated that "it had succeeded far beyond any other remedies of its kind, and showed results so perfect that it was impossible to know that any treatment had been carried out." It is impossible to accept the incorrect statement of your commentator that London paste applied to the tonsils is "followed by fibrosis and scar formation which seals up the crypts and causes retention of secretion in the remainder of the tonsil," and that after such treatment dissection of the tonsil is more difficult. This implies that patients so treated require later to undergo surgical removal, which is not the case. I dispute such statements; for it is the entire absence of these disadvantages which makes this treatment stand out so conspicuously as compared with the results obtained with galvanocautery and diathermy. The case for London paste is that it has a predilection for the lymphoid tissue of the tonsil, which is the seat of the sepsis, and this is gradually destroyed by a piecemeal process of disintegration or necrosis, aseptic in character (confirmed microscopically by the late Prof. Shattock), layer by layer down to the capsule, opening up and levelling down the crypts and canals—certainly not sealing them up and encysting the secretions. There is no inflammatory reaction or formation of fibrous tissue, and the capsule is left intact, supporting the pharyngeal walls and acting as a barrier against outside infection. Far from such treatment being a discredit to the profession, my experience is that patients cannot thank one enough for saving them from the loss of time, discomfort, or pain of surgical removal and their pockets from the expense of nursing homes, etc.

Sulphanilamide and Calamine for Pyogenic Skin Infections

Dr. A. D. FRAZER (Nottingham) writes: Calamine lotion has long been used for the treatment of impetigo. A little over a year ago I started adding 4% of sulphanilamide to the lotion and found that cases cleared up much more rapidly. A series of cases was tried on 6% of sulphanilamide and a further series on 6% of sulphathiazole without improving on the results with the original strength. This sulphanilamide lotion has now been used in a large number of pyogenic skin infections, such as impetigo, septic sores, septic dermatitis, and streptococcal fissures, and has resulted in rapid cure in practically every case. Sycosis barbae is improved but not cured, but cures have been obtained in pustular folliculitis of the scalp. The lotion is very drying, and if its use is to be prolonged over one week it is wise to use a suitable ointment for one or two days before continuing. I write in the hope that others may try this method of treatment.

Bleeding after Tooth Extraction

Dr. H. THISTLETHWAITE (Sedburgh) writes: I see in the *Journal* of July 3, p. 30, advice on the treatment of bleeding after tooth extraction. My wife, who is a dental surgeon, was recently asked to extract teeth for a man with a very bad record of haemorrhages. Following information of some recent research, she gave him a short course of bloater-paste sandwiches. The bloater paste is stated to contain vitamin K. The extractions were carried out with minimal bleeding. I myself have had most gratifying results from "stypven," even in a case of arterial secondary haemorrhage four days after the extraction. No other treatment was needed.

Mycotic Nails

Dr. J. E. M. WIGLEY (London, W.1) writes: I would like to comment on the answer given to the question of the treatment of mycotic infection of the nails (Aug. 14, p. 221). It has been my almost invariable experience that simple removal of the infected nails, even when followed by the thorough cauterization recommended in your answer, does not have the desired effect of curing the condition. It also runs the obvious risk of causing an intractable dermatitis about the nail folds and surrounding tissues, thus making the cure worse than the disease. I have found that it is necessary to have the nails removed in such a way that it is made quite certain they will never grow again. My invariable practice is to request the co-operation of a surgeon, making the point of the total removal of the nails quite clear. I understand from my surgical colleagues that this operation entails the dissection of the nail bed, and that it is quite frequently necessary to remove a portion of the terminal phalanx as well. I know that this operation involves some shortening of the fingers or toes, whichever are involved, but there is practically no ensuing deformity, and nailless fingers or toes are better than infected nails. I have been told in a personal communication from a leading plastic surgeon that the finger-ends can be so dealt with that artificial nails can be worn if this is considered essential from a cosmetic point of view. My attention was first called to the real necessity for curing these cases by the appearance at one of my

hospital out-patient clinics of a man who had had mycotic infection of the finger- and toe-nails for over 20 years. His nails had been removed on at least three occasions with subsequent treatment of the nail beds, and on each occasion they had been infected on growth. Both his wife and grown-up daughter had contracted mycotic infection of their finger-nails, without doubt from him. I know it seems a drastic performance to lose the finger- or toe-nails permanently for what does not sound a very serious infection—"ringworm of the nails"—but I think my experience with the case I have just quoted, which I feel certain cannot be unique, sufficiently strong support for my point of view.

Journals for Enemy Prisoners of War

Dr. J. R. BAKER (Burnt Oak, Kidlington, Oxford) writes: I want to thank the many readers of the *British Medical Journal* who have sent journals and papers on medical and scientific subjects for enemy prisoners of war. The most useful contributions are copies of *British Medical Journal*, *Lancet*, and other journals of general medicine received within a month of publication, but of periodicals, as well as reprints and books, are gratefully received. The *Lancet* should be sent to Mr. H. V. Thompson, Department of Zoology, University Museum, Oxford, and the *British Medical Journal* and other papers to me at the address given above. It is a great help when senders write their names and addresses ("Anon") on the outside of their packages, together with letters S.P.P. (which stand for Scientific Papers for Prisoners of War). Readers who can send any journal regularly, week by week, after they have finished with it, are asked to send me a postcard, so that I may explain how it may be sent directly to a prisoners camp.

Treatment of Tapeworm

Col. S. HAUGHTON (Haddenham, Ely) writes: With reference to the answer on treatment of tapeworm given at page 157 of the *Journal* of July 31, I would like to stress that the treatment recommended, if adopted, will fail in the majority of cases of tapeworm. It is merely textbook teaching. It will not give anything like 100% cure, for this reason: the one essential of treatment is starvation of the patient, which includes starvation of the worm. The treatment recommended is a light diet for the patient but a very nourishing one for the worm. May I be emphatic and state that ideal treatment must include a minimum of 60 hours—i.e. 2½ days' complete starvation; water only. It is this:

(1) Last meal, say, Saturday evening, 7.30. Castor oil one ounce at bedtime. Bed for 3 days. (2) Sunday and Monday: Water only; nothing except sod. bicarb. ½ t.s. (3) Tuesday morning: (a) Extract male fern in capsule at 7, 7.30, 8, and 8.30 a.m.; a minimum of 90 minims, and maximum of 120 minims for adults is necessary. Note.—Only fresh extract of male fern to be used. It is useless to expect good results with extract which may have been open for months or years. (b) Castor oil one ounce 11.30 a.m. (c) Tea and bread-and-butter at 12 noon.

The above treatment starves the patient and the worm effectively so that the male fern will be absorbed by the worm. I know of no other treatment that gives 100% cure; but 60 hours' starvation is essential. I have been infected twice and have treated hosts of patients in 30 years, as above, successfully—one treatment on the head of the worm is hard to find; there may be more than one worm. There is only one criterion of cure, and that is to wait 2½ months and inspect stools daily for one month. Carbon tetrachloride cannot be compared with starvation treatment and the extract of male fern.

Midge Bites

Dr. PERCY TATCHELL (London, S.W.5) writes: Isn't the simplest remedy the best—if it works? I was stopping at a country gentleman's house and we were talking about midge bites. A former nurse said, "The best thing for that is boric acid lotion." The gardener outside was being tortured to death: his arms were a mass of bite so we gave him some. "How did you get on with that?" I asked him later. "They ain't been near me," he said, "since I put it stuff on."

Alopecia Areata

Dr. L. J. PAVILLET (London, W.2) writes: In 1924 in Essex I had as a patient a young man suffering from this unsightly trouble. His hair patched and patched until it was almost gone. I left him in the district but returned in some two years or perhaps a little more and he came to see me. The whole of the hair on his scalp had grown again thick and heavy, and he had had no treatment whatsoever. This, I understand from my readings, is what may be expected in these days.

Correction

In the debate in the House of Commons on women in national service (Aug. 21, p. 252) Dr. Edith Summerskill said that "the women in the Services paid the same rate as men were doctors." We are asked to state that women dental surgeons with the Army Dental Corps are also paid at the same rates as men.

LONDON SATURDAY SEPTEMBER 25 1943

METHODS OF ARTIFICIAL RESPIRATION

BY

D. G. CORDIER, M.D.

Professeur Agrégé de Physiologie et de Thérapeutique Générale (Alfort, Paris)

PART I

CRITERIA OF EFFICIENCY OF DIFFERENT METHODS

Recent articles in the *British Medical Journal* (Gibbens, 1942) and the *Lancet* (1943) raise the much-discussed problem of the efficiency of different methods of artificial respiration. After an examination of Table I in the article by Gibbens it seems necessary to restate the present knowledge of this subject; otherwise it is hardly possible to explain the great variations in his figures. In any case it seems better to try to give a physiological explanation than to admit that "the almost ideological frenzy in the attacks of the opposing advocates leaves the impression that it is the nationality of the promoter which determines the choice of method" (Gibbens).

General Principles

All methods must, theoretically, obey the following requirements: (1) give sufficient pulmonary ventilation—i.e., as nearly as possible the ventilation of a normal subject at rest; (2) stimulate the heart and circulation to help respiratory exchanges and transport of oxygen to tissues; (3) be harmless in themselves, easy of execution, and rapid in attaining results.

To judge the physiological efficiency of the methods various tests have been used, the most important of which are: (1) determination of pulmonary ventilation and respiratory exchange; (2) radioscopic and radiographic control; (3) manometric values of cardiac pressures during inspiration and expiration; (4) control of blood movement in the circulatory system. In this paper I deal only with the test of ventilation, the theme of recent discussions.

Nearly all investigators have held the determination of pulmonary ventilation to be a test of the utmost importance. In the table given by Gibbens the results have been obtained by quite different experimental techniques—some on subjects who had voluntarily suspended their breathing, others on subjects in apnoea, first produced by voluntarily forced breathing, and others, again, on subjects who had just died and in whom rigidity had not yet taken place.

Determinations in Voluntary Suspension of Breathing

The first part of Table I shows the widely varying results obtained by various experimenters on subjects who have voluntarily suspended their breathing while artificial respiration is applied. It was the British "Suspended Animation" Committee which, in 1903, decided that Silvester's method would produce a larger ventilation than Schäfer's. Schäfer did not believe that the techniques made it possible to judge the efficiency of the different methods. He considered it evident "that it is possible by nearly all the methods investigated to obtain an exchange of air per respiration as great as that of the tidal air." Schäfer's conclusions retain their value. Physiologists who have carefully studied respiration know that normal subjects, even when accustomed to respiratory tests, are completely incapable of neutralizing their breathing during the experiment and cannot be entirely passive all the time. This is the fundamental reason which explains the great difference in the results obtained as shown in part 1 of the table.

Determinations on Subjects in Apnoea

In order to obtain more passivity in the subjects certain experimenters applied artificial respiration during the short period of apnoea which follows a carefully studied period of voluntary forced breathing. In these conditions the quantity of air which enters the chest at each artificial respiration is

TABLE I

Experimental Conditions	Author	Lung Ventilation in c.cm.	
		Schäfer's Method	Silvester's Method
1. Subjects having voluntarily suspended their breathing	"Suspended Animation" Committee (1903) Schäfer (1904) Burton-Opitz (1922) Ploman (1906) Hamburger (1909) Liljestrand <i>et al.</i> (1913) Eve (1932) Killick and Eve (1933)	366 520 504 (average) 500-600 616 500 1,000 350-550	458 178 — 1,200-2,000 453 540 — 200
2. Subjects in apnoea	Liljestrand <i>et al.</i> (1913) Héderer (1934)	170 100-150	190 250-250
3. Non-rigid cadaver	Héderer (1934) Bruns (1927) Bruns and Thiel (1930)	40-50 20 20	200 200 200
4. Apnoeic patients in moderately deep anaesthesia	Waters and Bennett (1936)	2 females, 180 (average) 2 males, 662 (average)	214 (average) 933 (average)

shown to be much less than during artificial respiration when the subject has voluntarily suspended his breathing. Details concerning the Hering-Breuer reflex and "chemical" control of breathing can be found in the excellent work on *Respiration* by J. S. Haldane and J. B. Priestley (1935; Clarendon Press, Oxford).

The important point is that after a carefully studied period of voluntary forced breathing the passivity of the subject is much greater than when the subject voluntarily suspends his breathing. This is shown by the fact that the volume of air entering the chest at each artificial respiration is independent of the frequency of the artificial breathing, while with voluntary suspension of natural breathing the entering volume of air varies inversely with the frequency. In these conditions the results shown in part 2 of the table indicate that Silvester's method ensures a greater ventilation than Schäfer's. The technique gives better and more constant results than that which utilizes the subject who voluntarily suspends his breathing. The "Suspended Animation" Committee forty years ago observed:

"It occurred to the Committee that it might be feasible to carry out the inquiry upon the living subject, the conditions necessary being that the subject should remain completely passive for the short period of time during which the experiment might last, and that he should not, by involuntary closure of the glottis, prevent the free passage of air into or out of the lungs. The first of these conditions can be readily fulfilled if the subject immediately prior to the experiments makes several deep respirations and the *besoin de respirer* is absent. Under these circumstances it is by no means difficult to perform artificial respiration for a short time without any resistance on the part of the subject, and without his making any spontaneous movements of respiration."

Determinations on the Cadaver and in Anaesthesia

In 1908 Schäfer summed up the position with regard to artificial respiration on the cadaver by stating that the experiments were mostly futile by reason of post-mortem rigidity. Other causes besides rigidity may interfere with the results: these include pre-mortem circulatory stasis, pulmonary or non-pulmonary origin of death, abdominal meteorism, and age and corpulence of the subject. By operating on non-rigid cadavers after tracheal intubation, Bruns, Bruns and Thiel, and Héderer obtained greater ventilation with Silvester's method than with Schäfer's, as shown in part 3 of the table.

In 1936 Waters and Bennett made a comparative study of different methods of artificial respiration on males and females. They used patients brought into apnoea by exaggerated minute-volume respiratory exchange while in moderately deep anaesthesia. The low carbon dioxide content resulting from such a procedure sufficed to prevent voluntary respiratory movements while the skeletal muscles were completely relaxed. These workers obtained a greater ventilation with Silvester's technique than with Schäfer's (part 4 of table), and they believe their findings to be a definite contribution because "an apnoeic patient under deep anaesthesia . . . exactly simulates the candidate for resuscitation by artificial respiration."

Conclusions

Taking into account the different techniques which may be relied upon for the comparative study of manual methods of artificial respiration, it seems justifiable to say that all experimenters agree that Silvester's method introduces in the respiratory tract of the apparently dead subject the biggest volume of air. But it is necessary to emphasize again that the determination of ventilation is only one criterion in judging the efficiency of these methods. The choice of a method depends also on the causes of asphyxia. In previous papers I have insisted on the advantages and disadvantages of Silvester's and Schäfer's methods and their possible improvements.

PART II

TILTING STRETCHERS VERSUS MANUAL METHODS OF ARTIFICIAL RESPIRATION

In 1932 F. C. Eve published an article on a new method of artificial respiration in which the patient lay on a rocking stretcher and the weight of the abdominal contents pushed the diaphragm alternately up and down. He believed that this movement of the diaphragm was sufficient to ensure lung ventilation of normal value. More recently articles have appeared suggesting the great superiority of Eve's method over other methods of artificial respiration. Gibbens (1942) writes:

"Many otherwise uninjured men are rescued after only a short immersion and yet do not survive. This is undoubtedly because the normal methods of artificial respiration are not very efficient, need many skilled men, and are so tiring that they are not carried out thoroughly or for long enough. It was a relief to read of Eve's rocking method, which can be practised by unskilled men, efficiently and with little fatigue . . . Killick and Eve have given detailed figures which show the rocking stretcher's superiority over other methods, and it is eminently practicable at sea."

It is true that there are certain practical advantages in Eve's method, but its physiological superiority remains to be proved. The experiments so far made to demonstrate its efficiency are very few, and in my opinion fall short of proof.

Experimental Results with Eve's Rocking Method

In his article in 1932 Eve studied experimentally the effect of his rocking method on the lung ventilation of a subject voluntarily suspending his breathing. He found that each see-saw movement of the stretcher produced a lung ventilation of 1,500 c.c.m. Schäfer's method applied to the same subject produced a ventilation of 1,000 c.c.m. per respiration. The radiographic control of the chest in the subject voluntarily suspending his breathing during rocking showed a diaphragmatic excursion of 5 cm., which, according to Eve, indicates roughly a movement of 1,800 c.c.m. of air. In the following year Killick and Eve, again experimenting on subjects voluntarily suspending their breathing, found much smaller values of lung ventilation. Using the rocking method at rates approximating to the normal respiratory rate, the tidal air was 450 to 600 c.c.m. They also

found Schäfer's method less efficient than had been shown Eve a year before, and wrote that it produced a tidal air var in different subjects from 350 to 550 c.c.m.

These very different results obtained by the author of method are no more surprising than the similarly different results obtained by other experimenters who have studied efficiency of the various manual methods of artificial respiration on subjects voluntarily suspending their breathing. This technique of investigation is inconclusive because normal subjects even when accustomed to respiratory tests, are completely incapable of neutralizing their breathing during the experiment and cannot be passive all the time. The lack of passivity in subjects experimented upon by Killick and Eve is shown the fact that the volume of air entering the chest at artificial respiration varies inversely to the frequency, as brought out in Table II, drawn from the experimental results of these investigators.

TABLE II

Rate of Rocking (R) per min.	Volume of Ventilation per min. (litres)	Tidal Air in c.c.m. per See-saw
Without (R)	5.2	
6-7 (Rs)	5.4	830
10 "	6.1	610
14-15 "	6.6	450
20-22 "	8.5	400

Table III shows that results comparable to those of Kill and Eve are obtained when the rhythm of the respiratory movements is varied during artificial respiration produced manual methods in a subject voluntarily suspending his breathing. Moreover, the volume of tidal air is practically the same as that observed in normal breathing.

TABLE III

Respiratory Rate per min.	Schäfer's Method		Tidal Air (c.c.m.) Normal Breathing (Ventral Position)	Silvester's Method		Tidal Air (c.c.m.) Normal Breathing (Dorsal Position)
	Vol. of Vent. per min. (litres)	Tidal Air per Movement (c.c.m.)		Vol. of Vent. per min. (litres)	Tidal Air per Movement (c.c.m.)	
6	—	—	—	4.9	810	830
10	6.25	630	660	6.15	610	590
15	7.50	500	510	8.15	450	450
20	8.60	430	430	10.25	340	390

A glance at these tables shows that the experimental basis on which Gibbens relies as proof that the rocking method is superior to the other methods of artificial respiration is insufficient.

In 1936 Waters and Bennett studied comparatively the efficiency of the methods promoted by Eve, Schäfer, and Silvester on patients brought into apnoea by exaggerated respiratory exchange while in moderately deep anaesthesia. They stated "An apnoeic patient under deep anaesthesia, we believe exactly simulates the candidate for resuscitation by artificial respiration." Unfortunately, their experiments were carried out only on four subjects, and one single experiment was made to compare Eve's method with those of Schäfer and Silvester. This experiment was made on a woman, 47 years of age, whose vital capacity was 2,200 c.c.m., and in this subject rocking through an angle of 60 degrees (the angle of tilt in the work of Killick and Eve was 50 degrees) produced a lung ventilation of 100 c.c.m. In the same subject Schäfer's and Silvester's methods produced respectively a lung ventilation of 160 and 140 c.c.m. That single experiment during which small ventilations were obtained does not suggest the superiority of Eve's method, and should be repeated on various subjects. Nor do the results obtained by Eve and Killick on subjects voluntarily suspending their breathing permit us to state definitely that the rocking method is the best. Eve's method may be physiologically excellent, and certainly it deserves thorough study. What are the experimental criteria which enable us to judge its comparative efficiency?

Criteria of Efficiency of the Rocking Method

In judging the efficiency of Eve's method very important information can be obtained by studying lung ventilation of subjects in apnoea, on apnoeic patients in moderately deep anaesthesia, and on the non-rigid cadaver. A comparative study is necessary on each subject, using in turn the methods of Eve

Schäfer, and Silvester; and these studies, made on man, ought to be completed by experiments made on large monkeys after curarization. The comparative study of the various methods could be made (1) when the animal's breathing is stopped but cardiac activity remains, and (2) when breathing and heart-beats have stopped. The study of lung ventilation, chemical composition of expired air, gaseous exchanges, and percentage saturation of haemoglobin with oxygen in arterial and mixed venous blood would give very important indications of the efficiency of alveolar ventilation. It seems also absolutely necessary to study the influence of the angle of tilt on lung ventilation. If the weight of the abdominal contents actuates the diaphragm we may deduce that the volume of lung ventilation must be in relation with the angle of tilt.

A second criterion derives from radiosopic and radiographic study of the chest. This study must be made in the same experimental conditions as those used for the measurement of lung ventilation (subjects in apnoea, apnoeic patients in moderately deep anaesthesia, non-rigid cadaver).

One of the aims of artificial respiration is to stimulate the heart and circulation in order to produce oxygenation of the blood and to supply oxygen to the tissues. Artificial respiration creates an indirect massage of the heart, the intensity of which is shown by differences of pressure in the cardiac cavities during inspiratory and expiratory movements. The measurement of intracardiac pressure made on the non-rigid cadaver indicates that a quick see-saw flow of the blood takes place in the heart cavities, producing a true endocardiac massage. This mechanical stimulation certainly plays an important part in the restarting of the heart's activity. The various manual methods of artificial respiration are far from having the same efficiency on the cardiovascular system. Table IV shows the differences of pressure produced in the left ventricle of the non-rigid cadaver by various methods during inspiration and expiration.

TABLE IV

Method	Lung Ventilation in c.cm. (Non-rigid Cadaver)	Pressure in Left Ventricle (cm. Water)		Difference (cm. Water)
		Inspiration	Expiration	
Silvester (without expiratory compression) ..	200	-8	+1	9
Silvester (with expiratory compression) ..	250	-8	+18	26
Schäfer ..	20	+9	+13	4
Combined method: Schäfer's method with raising of elbows ..	210	-7	+15	22

A study of Table IV shows that the manœuvres of artificial respiration which mobilize the thoracic framework above and below its position of equilibrium—i.e., which provoke an active inspiratory enlargement of the chest and then an expiratory compression—are the most efficient, both on the cardiovascular and on the respiratory system. Silvester's method with expiratory compression and Schäfer's method improved by the addition of an active inspiratory movement (raising the elbows) fulfil these conditions.

The feeble action of Schäfer's method on respiration and circulation can be explained by the conditions of the respiratory system. In the cadaver (and in the apparently dead body) all the reflexes have disappeared, the muscles are slack, and the loss of tonus in the respiratory muscles brings the chest into the complete expiratory position; the diaphragm is relaxed and arches into the thorax.

As a result of these changes the lungs are almost entirely emptied of air and the capacity of the thoracic cavity is much diminished. Therefore the conditions of the respiratory system in the apparently dead body do not lend themselves to methods of artificial respiration which use only expiratory pressure on the thorax and abdomen, since the respiratory system is already in the greatest possible state of expiration. The ventral position in Schäfer's method further exaggerates the diminution of the capacity of the thoracic cavity, because the weight of the spine, shoulder, and back muscles contributes also to the collapse of the thorax. The strong pressure (+9 cm. water) registered in the left ventricle of the non-rigid cadaver lying on the abdomen and the slight manometric oscillations resulting from the manœuvres of Schäfer's method show the complete collapse

of the chest and the resulting compression of the heart. The state of collapse of the respiratory system of the apparently dead body explains completely why Schäfer's method, which compresses the abdominal viscera in the chest, utilizing the piston-like action of the diaphragm to expel the lung contents, has such a slight result on ventilation and circulation. As the rocking method is based on the same principle of stimulation of the inert diaphragm (by the weight of abdominal contents instead of abdominal compression as used in Schäfer's method), and the subject lies on the stretcher in the ventral position, it seems to me necessary to study the efficiency of Eve's method on the cardiovascular system of the apparently dead body.

The measurement of intracardiac pressure on the non-rigid cadaver during rocking and a complete study of the physiology of the circulatory system in large monkeys after curarization (measurement of arterial and venous blood pressure, circulation time, output of heart) under the same conditions as to rocking should yield information of great practical value.

Conclusions

Eve's rocking method certainly has great practical advantages, but the experimental criteria so far employed to study its physiological efficiency seem to me insufficient to prove its superiority to other methods of artificial respiration. A more complete experimental study is necessary before its efficiency can be determined.

MANAGEMENT OF ACUTE PLEURAL EMPYEMA

BY

P. R. ALLISON, Ch.M., F.R.C.S.

Honorary Thoracic Surgeon, General Infirmary at Leeds

The treatment of pleural empyema, whether it be acute or chronic, is simple drainage, and the drainage must remain adequate for as long as there is an abscess cavity. This is a surgical principle which applies to collections of pus anywhere in the body, but it is a principle which, in the case of intrathoracic pus, is in danger of being submerged by a constant flood of new-fangled drainage tubes, new irrigation apparatus, water pumps, and electric suction. The time at which an empyema should be drained is a matter for clinical judgment. The wise surgeon does not incise an infected area until the inflammation is well localized, and this too is applicable to pleural infections. Considerations of cardio-respiratory physiology may call for relief of pressure within the chest before drainage is advisable, and in such circumstances repeated aspiration of an infected pleural effusion may be necessary. Aspiration should be performed frequently, slowly, and without air replacement. In certain cases the same conditions may call for a water-sealed intercostal drain. When an empyema is ready for draining a liberal incision should be made, at least 2 in. of rib removed-subperiosteally, and a tube inserted. Only the skin should be sutured. At operation

the pus should be evacuated and any fibrinous masses removed, so that they do not block up the tube. In such cases nothing more than an "open drain" is needed. Any system of closed drainage tends to focus attention on the apparatus rather than the empyema cavity. When drainage has been started—and that word is used advisedly—all that is required to maintain it is a piece of rubber tubing, a safety-pin, common sense, and what the gardeners call green fingers. There are many other useful devices for post-operative treatment, and the thoracic surgeon should have them all if he is to play his appointed part; but these things are no more than useful labour-saving accessories.

Why has empyema acquired such a bad reputation for false healing? Subphrenic, perirectal, and bone abscesses have a similar reputation. In all these the walls of the cavity are not equally elastic, and in three of them they are constantly being varied by the movements of the intercostal muscles, the diaphragm, or the pelvic diaphragm. In the pleural abscess there may be still further inequalities due to scarring in the underlying lung or thickening of the interlobar septum. These factors make for irregular healing and the creation of dead space, so that drainage which is adequate one week may be inadequate the next. The daily dressing of such cases is therefore a matter for a skilled and interested doctor rather than a nurse. Ideally the initial drainage operation should be done by the doctor who is prepared to do the daily dressings.

Causes of Inadequate Drainage

At any time during the post-operative period drainage may become inadequate, and an investigation into the cause of this will probably reveal one of the following:

1. Obstruction by Fibrinous Masses within the Drainage Tube

Where an intercostal drain or a minimal rib resection has been performed masses of fibrin may be left either loose or hanging to the walls of the cavity. Pieces of this may enter the lumen of the tube and block it up partially or completely. The amount of this material varies, but it is found particularly in the pneumococcal empyemas of children and those in which operation is long delayed. Sometimes the cavity is occupied by a mould of fibrin in which are lacunae filled with pus. A high solid content is also found in the empyema which results from an infected haemothorax and in the pleura after pneumonectomy that becomes infected through a bronchial fistula. Sometimes fibrinous masses form during drainage, and this is seen particularly in empyema complicating bronchiectasis. There should be no interference with drainage if the cavity is well cleared out at operation and if the tube is removed each day, sterilized, and put back. Gentle irrigation of the cavity with Dakin's solution may help, but the operator should be certain that bronchial fistula is not present. It should be done through a soft rubber catheter of such dimensions that there is ample room for the return of the displaced air between it and the sinus wall. If fluid is forced into an empyema without adequate provision for escape there is a danger of air embolism.

2. Obstruction by Granulation Tissue

One advantage of a simple open drain is that the tube may be removed, cleaned, sterilized, and replaced each day. If such a tube is left in too long healing may take place over the end and a plug of granulation tissue completely obstruct the lumen. If there are lateral holes in the tube, granulation tissue may grow into these and have a similar effect. In the same way the end of a self-retaining tube is even more likely to become obstructed, as there is a natural tendency to leave these in place much longer on account of the unpleasantness associated with repeated removal. It is not always possible to avoid such obstruction by daily irrigation, as the granulations are often in the form of a polyp, which may be temporarily displaced by irrigation only to fall back into the opening afterwards. Whatever sort of tube is used the danger of this type of obstruction is much increased by any form of suction.

3. Obstruction by Kinking of Tube

Kinking of the tube may occur where a drainage sinus is tortuous, or it may happen in the tissues of the chest wall or,

where closed drainage is used, between the chest wall and the bottle. Such an accident is particularly liable to happen at the point at which a lateral hole is cut in a tube, and is a much more frequent occurrence with the present poor-quality rubber.

4. Tube too Short to Reach the Pleura

It is not an uncommon thing for an uninstructed nurse or house-surgeon to undertake the daily duty of cutting half an inch off the drainage tube, so that in a very short time the tube no longer reaches the cavity it is meant to drain, but lies uselessly in the chest wall. At other times a tube may come out accidentally and be left out for a few hours. In this very short time the chest sinus becomes narrowed, especially in the plane of the periosteum and intercostals. The tube is then often put back as far as it will go easily and the rest cut off. Where closed drainage has been used the tubing connecting the patient to the underwater drain is often anchored to the bed in some way, and it may then happen that a sudden movement by the patient may pull the self-retaining head of the tube out of the empyema cavity into the soft tissue of the chest wall.

5. Tube through the Chest Wall but not reaching the Cavity

This happens only as a result of healing of the empyema. At first the tube may be perfectly placed, but, as a result of elevation of the diaphragm, expansion of the lung, or both, the base of the empyema may heal more rapidly than the upper part, until a cavity is left above communicating with the tube by a long narrow track which is quite inadequate for drainage. This condition is seen particularly in those large empyemas involving the apex of the pleura. In these the expansion of the lung often seems most rapid in the subapical region, so that a residual apical cavity may come to communicate with a basal drainage opening through a narrow sinus 6 or 7 in. long. In these cases the tube must be lengthened in order to pass beyond the constricting area into the cavity. The part below this may then drain through lateral holes in the tube.

6. Tube too Far into Cavity

With both a simple tube and a self-retaining tube the inner end may be so far into the cavity that pus collects below it and only drains as an overflow. In the case of the open drain it is not satisfactory to have a tube which just reaches the pleura, because of the danger of its slipping out. The safest thing is to have the tube projecting a short way into the cavity and to cut a lateral hole in it at the point at which it enters the pleura. As will be mentioned again, it is important that the length of the tube and the position of the lateral hole should be constantly reviewed in the light of changes which the draining sinus undergoes during healing. As the floor of the cavity rises the sinus becomes longer and the lateral hole becomes ineffective. The inner end of the tube may then be above a fluid collection once more. Where a self-retaining tube is used in conjunction with a water-sealed drainage system a similar state of affairs may be produced in a different way. When the tube is first inserted a safety-pin should be passed through it at the skin level or at least in such a way as to allow a small thickness of gauze between the pin and the skin. If this is not done the tube easily works upwards with the movements of the patient and pus collects in the bottom of the cavity. Even when a pin is inserted it needs frequent changing in order that the skin round the wound may be properly cleaned, and it sometimes happens that a patient may lean on the tube while the pin is out, and so push it further into the cavity. Unless it is pulled down before the pin is inserted pus will collect around the stem of the tube.

7. Part of the Cavity Below the Drainage Opening

Where an empyema cavity has a broad base it is often difficult to decide on the best position for the tube. Sometimes the floor of the cavity is curved so that the anterior and posterior ends are both on a lower level than the middle. In such a case it may be wise to insert two tubes—one in front and one behind. Where only one is used either the anterior or the posterior end may remain dependent and be occupied by a puddle of pus which never drains away completely. Similar conditions sometimes occur because the drainage tube is not inserted with a view to the ultimate position of the

patient sitting up in bed or walking about the ward. The finding of a dependent part of the cavity is not, however, always a reflection on the placing of the tube, for it may result from the way in which the empyema heals. One example of this may be described. An empyema cavity heals from the edge centripetally. All along the line of junction of visceral and parietal pleura adhesion takes place, gradually pulling out the lung to the chest wall. If the empyema involves the diaphragmatic surface, and if it does so more in front than behind, then the line of junction will reach the chest wall behind first and continue to climb up the chest here while in front it reaches the chest wall later and so lags behind, the front part then becomes dependent from the drainage sinus. The condition can easily be diagnosed by tilting the patient into various positions and finding at what angle the pus starts

resection operation than to use any force in the dilatation of such a sinus. Where force is used there is danger of air embolus, temporary paralysis, or cerebral abscess. When the drainage tube is removed there may be an immediate flow of pus, and this indicates that the tube is too long. It is better in such circumstances to cut a series of lateral holes in the tube rather than to shorten it until a radiograph is available. It is sometimes possible to measure the length of the sinus by passing in a coude gum-elastic catheter and gently withdrawing it until the bent end catches on the rim of the sinus opening into the cavity, but it is simpler still to explore with an instrument that I have had made by the Genito-Urinary Mfg. Co., which can be passed through the sinus straight and be bent when in the cavity: this I call an "articulated empyema sound" (see Fig.).

The sound is passed into the cavity straight. The end is then bent as in the dotted line and the sound gently withdrawn to the rim of the cavity. The length of the sinus is then measured on the staff of the instrument. The length of tube required to drain the cavity is estimated from this.

to drain, or, more graphically, by injecting an opaque oil into the cavity and taking radiographs in the upright position. When the exact position of the dependent part has been located a second tube should be inserted here. It is usually wise in such a case to retain the original drain as well.

It must be remembered that from the point of view of an empyema the diaphragm forms part of the chest wall. Where the diaphragm is involved in an empyema the drainage opening must be placed lower than usual, and in fact the tube may often have to be placed in the usually forbidden zone of the costo-phrenic sinus. In such cases especial care must be taken to see that the tube is lengthened during healing, to prevent the diaphragm from becoming adherent to the chest wall over the end of the tube and leaving a cavity above. Such truly basal empyemas are sometimes, but not always, secondary to a peritoneal infection.

8. Loculation

When an empyema forms in a pleural cavity intersected by adhesions multilocular cavities may occur. This condition is not met with as often as might be expected. The loculi may be entirely separate, be joined through a very narrow channel, or have a fairly wide communication. In the first and second events drainage may be unsatisfactory from the first, but in the third it may become so by expansion of the lung at the waist of the hour-glass. This is a further reason for wide initial opening of an empyema, with careful note of its shape and size and the presence of any narrow channels, rather than the rib resection which is considered sufficient so long as pus is found and a tube inserted.

Tests for Cause of Unsatisfactory Progress

When an empyema is not progressing satisfactorily, therefore, what simple clinical tests can be made to find the cause? This is a problem which frequently faces the thoracic surgeon, often in conditions in which radiographic facilities are poor or absent. First, the patient should be sat upright in bed and the wound inspected. The presence of a sore skin, a rusty safety-pin, and large oedematous polyps of granulation tissue round the tube indicates neglect, and it can be assumed that the inside of the chest is equally unsatisfactory. The tube should be removed. If it is 1½ in. long and falls out easily it is certainly not in the cavity except in the case of small infants. In these circumstances a firm well-greased rubber catheter about size 10 should be passed into the sinus. This may find its way into a cavity without damage to tissues and with relief of pus. A series of catheters can then be passed gently until the sinus is wide enough to take a small rubber drainage tube. The length of catheter in the chest when pus flows is an indication of the length of the tube needed, but it is often safer to make the tube a little longer and cut a lateral hole at the measured length. It is unwise to probe such a sinus with metal or rigid gum-elastic probes except with the greatest gentleness and caution. It is better to subject the patient to a fresh rib-

If no pus drains away when the tube is removed the patient should be tilted into various positions to see if there are any dependent pockets. Another useful guide is to inject a known amount of saline into the cavity when the patient is lying on the good side, sit him upright, and measure the amount of fluid that drains away. There may be some resistance to the withdrawal of the drainage tube, and then it suddenly comes away. The lumen of the tube is found to be filled with wet granulations and the sinus bleeds from the tearing off of this unhealthy tissue. Pus may then drain freely, or it may be necessary to pass a catheter through terminal granulations to effect this.

Just as the experienced operator knows when a needle enters an empyema cavity even when the pus is too thick to be withdrawn, so the same fingers will learn much about a drained empyema by the simple passing of a soft rubber catheter. This is not something which can be passed on to house-surgeons, but something that they must learn for themselves. They should be encouraged to keep constant digital contact with their empyemas and only to use radiographs to verify their findings and to solve problems which exist after the simple clinical tests have been applied. Nothing that has been said must be taken to minimize the most valuable information that can be obtained by radiography. All thoracic surgeons are aware of the immense help obtained from radiographs in the treatment of empyema. In the first place straight radiographs in the upright position, both postero-anterior and lateral, are taken. These will show residual fluid levels, residual opacities, and their relation to the drainage tube. The next step is to fill the cavity with an opaque oil, close the drainage tube, and take further pictures. Finally the tube is allowed to drain in the upright position and further pictures are taken to see if drainage has been complete, or, if not, the position of dependent portions. The size, shape, and position of the cavity in relation to the drain are then known. The presence of bronchial fistulae, disease in the underlying lung, or undrained loculi can also be seen.

An uncomplicated acute empyema, kept properly drained and properly dressed, should pursue an uninterrupted course to recovery. With the help of the physiotherapist trained in thoracic work this should occur without skeletal deformity or impaired cardio-respiratory function. If such steady progress is interrupted by a febrile attack it would seem obvious that it is the responsibility of the surgeon to find the cause of the temperature. Too often, however, is the patient put on a course of sulphonamides, and many valuable weeks of convalescence are wasted and much unnecessary ill-health and discomfort caused. If a patient whose empyema has been drained becomes febrile the most likely explanation is that the drainage has become inadequate. There are other possible causes: cellulitis of the chest wall, which usually results from stitching up the muscles round the tube after rib resection; deep abscess of the chest wall following pre-operative aspiration; or a tube which is "ulcerating" into the lung itself. In

this last case it usually happens that the lung expands and impales itself on the end of the tube. The correct treatment may be either to remove the tube altogether or, if a cavity is still present, to put a longer one in past the site of ulceration. A lung will never ulcerate through contact with the smooth curved side of a tube, but only with the end of a simple tube or the relatively sharp projecting rim of a self-retaining tube. Other causes of temperature may be disease in the lungs or, very rarely, the development of another empyema, or some cause remote from the chest such as a sore throat. Fortunately are complications are meningitis, encephalitis, and brain abscess, but these things should be kept in mind during the investigation of a case.

Physiotherapy

Next in importance to the maintenance of adequate drainage through the whole course of treatment is the prevention of chest and spinal deformities with their resulting bad posture and impaired respiratory function. The picture of a deformed and rigid chest, with shortness of breath on exertion, dizziness, lassitude, lack of appetite, and even clubbing of the fingers, may closely simulate a chronic empyema and yet the lung may be uniformly adherent to the chest wall. I have seen all these signs and symptoms, including the finger-clubbing, disappear after a month's spinal and breathing exercises. Physical training, starting in a small way, should begin the day after operation. Special exercises have now attained a high degree of perfection. Those who have no highly trained personnel available to carry out this work should remember that any exercise which works the skeleton on the affected side is good. The lung should be forgotten and attention focused on the pectorales major and minor, the latissimus dorsi, the serratus magnus, intercostal, diaphragm, and abdominal muscles. Voluntary deep breathing is only followed by apnoea, but the deep breathing of healthy exercise is good, and for this reason the open drain is better than the closed, for it allows of long walks and hard work.

Placing of the Drainage Tube

When an acute empyema is ready to be drained by open operation the limits of the cavity should be ascertained as accurately as possible by aspiration of pus and the introduction of a little air. In this way a fluid level is formed, and radiological examination will show the exact position of the cavity. The tube should be placed so that it is approximately half-way between the anterior and posterior margins of the cavity, and the case of the more common basal empyema about level with the dome of the diaphragm. Though this position may be a little above the lowest point at which pus can be aspirated, it avoids placing a tube in the narrow costo-phrenic sinus, and it rapidly becomes occluded. The main exception to this is the one already mentioned in which the diaphragm is extensively involved in the empyema. Apical and axillary empyemas should be drained 1 in. above their lowest points. Chronic empyema should always be drained at its most dependent part.

Infected Haemothorax

A small infected haemothorax differs very little from the pneumonic empyema, but under war conditions it is not usual to find the whole pleural cavity involved. The very early infected haemothorax is generally the result of improper treatment of the original condition. Blood and bloody fluid in the chest which result from trauma should be aspirated out air replacement. They should be aspirated repeatedly frequently, so that if infection occurs it involves only a small area of pleura. The introduction of air serves no useful purpose and only increases the size of the pleural cavity which eventually needs drainage. When a lung has collapsed with a large infected haemothorax it may take as long as years to expand. It must be remembered that where infection takes place in a haemothorax loculi of fluid may form, some of these may be infected and some sterile, so that drainage in numerous places may be necessary. When infection is once established the chest should be opened, all clot removed, and adequate drainage established. The subsequent management is the same as for a post-pneumonic empyema. Healing may be delayed by scarring of the underlying lung tissue at the time of the injury.

EAR, NOSE, AND THROAT CASUALTIES IN A GENERAL HOSPITAL IN THE MIDDLE EAST

BY

E. G. COLLINS, F.R.C.S.Ed.

Major, R.A.M.C.

Every medical officer has two main duties. The first is to use every means in his power to practise prophylaxis; the second is to ensure that when disease does arise the maximum number of his patients return to a state of health which will fit them for all forms of active service in the shortest possible time. Such a policy applies equally to the specialist as to the unit medical officer, and it was felt that a detailed analysis of the casualties attending the ear, nose, and throat department of a general hospital in the Middle East might form the basis for some constructive suggestions as to how the incidence of the more prevalent conditions might be diminished, the period of admission to hospital decreased, and more adequate treatment in general instituted.

The period chosen was from Sept. 20, 1940, to Feb. 20, 1941 (approximately five months), and, though it is admitted that a longer period would have been preferable, further experience showed that, with the exception of war injuries, no appreciable variation occurred over two years. During the months under review war injuries affecting the ear, nose, or throat were few in number, and the type of disease encountered bore a close resemblance to that found in the ear, nose, and throat department of any hospital in the British Isles. There was, however, a definite alteration in incidence. Statistics make dry reading and for the purpose of this article it is proposed to abstract the more prevalent diseases only from the detailed analysis that was made of all the cases.

Out-patients

The number of out-patients who attended for the first time was 517. As the numbers in the area were constantly changing no useful information is obtainable from a comparison of attendance in the different months. The more prevalent diseases were:

(a) Aural Diseases

Disease	% Aural Cases	% Total Out-patients
Otitis externa, acute	20.70	10.25
" " " chronic	11.72	5.80
" " " media, acute	7.03	3.48
" " " chronic	27.73	13.73
(Ruptured tympanic membrane ..)	2.73	1.55

It will be noted that the gross percentages of otitis externa and otitis media are approximately equal.

(b) Nasal Diseases

Disease	% Nasal Cases	% Total Out-patients
Deflected septum	12.65	4.06
Sinus infection	66.87	20.31

Of the sinus cases 74% yielded to treatment by conservative measures, which included short-wave diathermy and repeated proof-puncture.

(c) Throat Diseases

Disease	% Throat Cases	% Total Out-patients
Tonsillitis, acute and subacute ..	54.65	10.25
" " " chronic	36.91	6.91

A large number of the subacute cases were patients sent down from the medical wards for an opinion on the advisability of operation. In a further 18% of out-patients who came up for different complaints some degree of chronic tonsillitis was noted, but not sufficient to warrant operation.

In-patients

It was found that the total number of in-patients admitted for ear, nose, and throat diseases was 11.35% of the total admissions to the hospital, and comparison with figures obtained from a military

hospital in peacetime showed that there was no relative increase as might have been expected during a war. The only comment that might be made is that the cases admitted were more of an emergency character. The admissions were analysed as follows: Total number of in-patients with ear, nose, and throat diseases, 537; admitted to medical wards, 350 (65%). Practically all of these were cases of acute tonsillitis. Admitted to ear, nose, and throat ward, 187 (35%). The cases comprised: otitis externa (acute and chronic), 19%; otitis media (acute), 16%; otitis media (chronic), 24%; sinusitis (acute), 11%; sinusitis (chronic), 6%; miscellaneous, 24%. Only three cases of ruptured tympanic membranes were admitted to the ear, nose, and throat ward, but many others were seen in the general surgical wards. Of these there is unfortunately no record available.

Operations.—The total number of operations performed was 171. Of these, 77 were for dissection of tonsils, 7 for cortical mastoid, and 6 for a radical or modified radical mastoid (3 had a fistula of the external semicircular canal). In addition intranasal drainage of the sinuses was performed on 18 patients, and 1 patient had a radical antrum operation (Caldwell-Luc).

It is proposed to discuss these various conditions in greater detail. Some of the suggestions made are already in force in the Middle East; others are purely personal, and have resulted from discussion of the problems with other otologists. These might be modified with further experience and information, but for the sake of obtaining a complete picture all have been included.

Otitis Externa

There is no doubt that the frequency of this disease is increased by service in the Middle East. As has already been shown, the cases of otitis externa and of otitis media are approximately equal in number. It is in its acute form that the disease interferes with the efficiency of the soldier, but there is no sharp line of demarcation between the acute and the chronic phase. With the least provocation the latter is liable to flare up and become acute. Especially is this the case when an associated chronic suppurative otitis media is also present and when the soldier is posted for service in the Western Desert. The aetiology of the disease still remains obscure. Dust, heat with its concomitant sweating, bathing, and, in the Western Desert, lack of water for personal ablution have all been mentioned as factors in its causation. Other possible causes are the high salt concentration of the water and an allergic origin due to focal sepsis. These aspects have been well reviewed by Daggett in an excellent article on cases which occurred at Malta. It seems possible that not one factor alone, but several, may be responsible, and that anything which favours the growth of organisms and the maceration of the skin may play a part. In a series of aural swabs examined the organisms found were diphtheroids, *B. proteus*, and *B. pyocyaneus*. The last-named was very difficult to eradicate. *Staph. aureus* was present in a greater proportion than was noticed in the Malta series, and the streptococcus was infrequent.

In acute otitis externa the soldier experiences very severe pain in the ear, there is scanty aural discharge, and the meatus is greatly narrowed and often pin-hole. It was noticed that there is often a deficiency of true waxy secretion, and the return of normal soft wax was regarded as one of the signs of cure, but whether this is of any practical significance is undetermined. Frequently there is an associated adenitis with considerable constitutional disturbance. In its chronic stage the disease is very resistant to treatment and apt to recur.

Treatment.—Many acute cases could be prevented or aborted if the soldier reported to the medical officer at the first sign of any aural discharge. The following suggestions are offered as prophylactic measures with some reserve, owing to our present lack of knowledge. It did, however, appear that some protection was afforded by the use of vaselined cotton-wool plugs inserted in the ears while bathing. Another important point is that great care should be taken in drying out the ears with any rough towel after bathing, and, if possible, it is better to use a pencil of cotton-wool. Bathing in swimming-baths appeared to be more harmful than bathing in the sea. Where there is an associated seborrhoeic dermatitis of the scalp it must be treated, but this was infrequent in the patients seen. It is not the purpose of this article to discuss local treatment in detail, but thorough cleansing of the external auditory meatus, and especially the recess near the antero-inferior part of the tympanic membrane, is an essential for success. Two applica-

tions that proved of value in the acute form were 10% ichthylol in glycerin, and 8% solution of aluminium acetate (Burow's). The latter was, however, practically unobtainable, and good results were reported from the use of 5% lead acetate. Medication is applied by means of a gauze wick. In the more chronic form a hydrarg. oxi-flav. paste was used with benefit. Ointments are contraindicated in a hot climate. A 4% solution of sulphanimide in sodium bicarbonate met with some success, though this would not be expected with the type of organism present. It is possible that when penicillin is available on a commercial scale we shall have a useful addition to our medication. When the disease frequently recurs or where there are gross hypertrophic changes in the meatus it is better for the otologist to board the patient for base or home service, as desert warfare is definitely contraindicated.

Otitis Media

Acute otitis media did not form a large proportion of the cases during the period under review, but there was a definite increase during the summer months—probably attributable to the greater use of the swimming-baths. The prophylactic measures include the avoidance of diving and of swimming under water when the soldier has a cold. The use of dirty handkerchiefs and incorrect blowing of the nose are other obvious causes: but perhaps the average "Tommy" is less liable to err than the officer, as he usually adopts the more physiological method of clearing his nose by sniffing rather than blowing. Treatment was greatly influenced by the oral administration of sulphonamides, and it was necessary to submit only 6 patients out of a total of 47 cases of acute otitis media to a cortical mastoid operation. This was undertaken more because of the continuation of the discharge than because of the acuteness of the symptoms. Chronic suppurative otitis media proved a more difficult problem. Whereas, in civil life, the soldier could carry out his work easily without paying much attention to aural discharge, on active service in the Middle East other factors proved important. His efficiency may be impaired by (a) deafness, which may be progressive in character, leading to the misinterpretation of orders; (b) the association of chronic suppurative otitis media with acute otitis externa; and (c) the occurrence of intracranial complications. Furthermore, a certain number of patients with chronic otitis media experience considerable pain or tinnitus on exposure to continuous rifle-fire, gun-fire, or explosions; but this is not a constant feature, and there appears to be an individual sensitivity. It would be more satisfactory if patients suffering from this disease were excluded from service in the Middle East, but as for various reasons this has proved impossible some scheme must be devised for their treatment. The following contains many suggestions that were already in force in the Middle East.

Scheme for the Treatment of Chronic Suppurative Otitis Media

1. **Role of the Otologist.**—(a) All patients with chronic suppurative otitis media should be seen at least once by an otologist, who would decide which patients needed recategorization, admission to hospital, "self-treatment" under the supervision of the unit medical officer, or treatment at an aural treatment centre.

(b) With regard to recategorization, considerable latitude was allowed the otologists in the Middle East, and it was possible to "board" a soldier for a period of three months for base duties only without resorting to a medical board. The actual fighting in the Western Desert was very mobile, and it must be recognized that in the middle of a battle the unit medical officer is not able to attend to the cleaning out of a patient's ears. Often his ambulance car or truck is never properly set up, and there is no established M.I. room. Consequently, more patients were graded for base duties than would have been the case in static warfare. This does not necessarily imply that every case of chronic suppurative otitis media should be graded for base service only, as the question of man-power must receive careful consideration. Some of the patients can clean out their ears quite well themselves if they have had a proper training. It is the duty of the otologist to decide which of these cases are suitable for this front-line method of "self-treatment."

2. **Role of the Unit Medical Officer.**—For some reason medical officers seem very much afraid of ear diseases, and it is a frequent occurrence for patients to be sent to the otologist without any attempt at a diagnosis. Perhaps this may in part be due to lack of equipment, but a certain amount is due to lack of knowledge and interest. Yet the ultimate responsibility for the condition of fitness of these patients rests with the medical officer. It is suggested:

(a) That a circular should be sent round to all unit medical officers containing an outline of the more common ear, nose, and throat diseases and established methods of treatment. This was done in the Middle East.

(b) That a short clinical course should be held at the ear, nose, and throat departments of the larger hospitals in the area. Not more than three officers should be attached to one hospital at a time, otherwise difficulty would be experienced in providing proper tuition.

(c) That it is the duty of the medical officer personally to instruct his patients in the proper method of "self-treatment." The procedure to be carried out would be included in the circular. In addition, it is suggested that the unit medical officer should be provided with "self-treatment" sets for distribution to his patients. These would contain 1/4 lb. cotton-wool (fine fibre), 2 dozen wood-wool applicators, and a 2-oz. bottle of boric acid in spirit drops with pipette, in a cardboard box. Instructions for use would be printed on the lids.

3. *Role of the Hospital.*—It is maintained that chronic suppurative otitis media is an "out-patient" disease and that any extensive "in-patient" treatment at hospital has a bad psychological effect, besides leading to a great wastage of valuable man-hours. Admission to hospital should be reserved for those cases in which the otologist considers the aural condition endangers the patient's life; others with obvious nasopharyngeal sepsis, the removal of which will give a reasonable chance of a dry ear; and a much smaller group of patients which the otologist desires to keep under observation for the treatment of aural granulations or polyps.

4. *Role of the Aural Treatment Centre.*—It has been shown that in 40 to 50% of chronic suppurative otitis media the aural discharge will clear up if adequate conservative measures are taken. At a meeting of otologists in the Middle East it was suggested that aural treatment centres should be established at the larger base camps. The centres would be staffed by a medical orderly who had received six months' training by the otologist at the ear, nose, and throat department of a general hospital and who was capable of using a forehead mirror. This may appear to be a counsel of perfection, but personal experience has shown that, provided a keen and intelligent orderly is chosen at the start, complete reliance can be placed on him to carry out the treatment properly. His capabilities will depend on how much trouble the otologist takes to train him. The centres would be under the supervision of the Ear, Nose, and Throat Adviser to the area, who would visit them at stated intervals, and adequate equipment would be provided. So far as was possible, units would be treated by appointment. The establishment of these centres would have the advantage of avoiding waste of man-hours and would counteract the difficulties of supplying the necessary equipment to every unit medical officer. In addition treatment should be more thorough, as all too often treatment is delegated by the medical officer to an untrained orderly who has neither the knowledge nor the equipment to carry it out efficiently. Many patients who have attended such a centre should in time be fit to be graded A, and others be able to carry out "self-treatment" once the ear has reached a more healthy condition.

5. *Forward Otological Service.*—This was established in the Middle East, and that it was necessary is shown by the fact that over 200 cases of chronic suppurative otitis media were seen at Tobruk every quarter. Some of these patients had escaped the net at the base, while others had been sent up on draft from the infantry case depot although graded B. There is a considerable amount of ear, nose, and throat work to be done in a forward area, and if the otologist possesses some knowledge of general surgery he can make himself useful when the battle starts.

Treatment.—It is necessary to emphasize that prophylaxis consists in the proper and adequate treatment of every case of acute otitis media. In local treatment it matters little whether the "wet" or the "dry" method is used so long as the ear is cleaned out thoroughly before any drops are instilled. The otologist should bear in mind that radical mastoid cavities are slow to heal in the Middle East and are difficult to keep clean. The modified radical mastoid operation is, where possible, the method of choice, but in all treatment as conservative a policy as possible should be pursued.

Finally, it is emphasized that the success of any scheme will depend on the full co-operation of the units concerned.

Acute Tonsillitis

Prophylaxis consists essentially in isolation. It is suggested that, in spite of the difficulties, every effort should be made to carry this out near the front line, and that only cases of frequently recurrent attacks of tonsillitis should be sent back to base. At a base hospital a special ward should be available for cases of tonsillitis only, even at the cost of empty beds. This ward should be in the charge of a medical officer who

is under the direct supervision of the ear, nose, and throat specialist—not, as at present, under the control of the medical side. Many patients are already referred to the specialist for the advisability of operation, and also, in a considerable number of cases, there is an associated "missed" sinusitis which leads to frequent recurrent attacks of tonsillitis, with readmission to hospital. It is suggested that there should be a small dark room attached to the tonsillitis ward with simple examination equipment available. It would be the duty of the ear, nose, and throat specialist to instruct the officer in charge of the ward in the methods of sinus investigation. Every case of acute tonsillitis should have the ears and sinuses thoroughly examined before discharge, and "missed" complications should not occur.

Treatment.—The infecting organism in the majority of cases in this area was *Str. viridans*; but in spite of this fact the administration of sulphanilamide definitely decreased the length of stay in hospital. Local treatment followed the usual line. Operation by dissection of tonsils was undertaken in 17% of cases. Care was exercised in reaching a decision, and only those patients who had suffered from three or four severe attacks were regarded as suitable candidates. Because of the difficulty in regaining contact with a patient once he has been discharged, operation was undertaken early (i.e., a fortnight to three weeks after the start of the attack). Experience showed that, while the incidence of secondary or reactionary haemorrhage was slightly increased, this was never sufficient to endanger life, and in only one case during the five months was it necessary to give a second anaesthetic to control the haemorrhage. It is maintained that the benefit derived from this extra week in hospital more than compensated for the time lost through frequent recurrences, and, in addition, the long waiting list was abolished. There is no doubt of the benefit in health received by the soldier in the removal of the toxic focus.

Sinusitis

The figures for this disease strongly suggest that there is a high incidence of sinus infection in the Middle East. Part of this must be attributed to the infected dust-laden atmosphere as there was a noticeable increase during a dust storm. Bathing in the swimming-baths appeared to have a deleterious effect, as even if the bacillary content was low the heavy chlorination practised had a harmful effect on ciliary activity in the nose. The prophylactic measures to be followed are outlined under the section on acute otitis media. Some doubt has been expressed as to whether Sluder's "vacuum" sinus headache is a real clinical entity. It can only be stated that this type of case was met with again and again in the Western Desert, where there were no clinical signs beyond a reddening of the mucosa of the middle turbinate and some tenderness on pressure over the sinus. The headache was definitely referable to one or other of the sinuses, and, even after exclusion of ocular, general, and psychological causes, a considerable number of patients remained. Clinically it did not resemble "vasomotor rhinitis," but an allergic factor may have been present.

Treatment.—A strong plea is put forward for conservative methods, such as inhalations with the use of ephedrine in saline sprays, headlight baths, short-wave diathermy, and repeated proof-puncture. It was found that 74% were cured by these means, and later experience in the desert confirmed the fact that operated cases did badly. It is probable that fewer cases still would have been submitted to operation had this experience been available at the start. Many in-patients with so-called "vacuum" sinus disease were improved by rest in bed and the ordinary conservative treatment of acute sinusitis, but the condition remained a definite problem.

Addenda

The following notes on some conditions are of interest:

1. *War Injuries.*—The number of war injuries seen during this period was small. It was noted, however, that there was a considerable proportion of war injuries to the ear among the general surgical cases, and an investigation was undertaken. The results, however, are not yet available.

2. *Deviated Septum.*—The opinion is held that during war the septum operation should be regarded as a "luxury"

measure except in the case of gross nasal obstruction or where forms a contributory factor in the causation of catarrhal eafness or sinusitis.

3. *Diphtheria*.—This was treated at one central hospital where there were special nursing facilities. The cases seen here, though few in number, were of marked virulence, and although antidiphtheritic serum was given early in adequate doses it did not appear to have the usual effect. Peripheral leucitis seemed much more common and severe.

Summary

An analysis is made of ear, nose, and throat casualties occurring at a general hospital in the Middle East.

The commonest diseases were acute tonsillitis, otitis media, otitis externa, and sinusitis.

Suggestions are made by which (a) the incidence of these diseases may be lowered; (b) the period of admission to hospital decreased; (c) more adequate treatment in general instituted.

Miscellaneous notes connected with ear, nose, and throat work are included.

My thanks are due to Col. H. J. A. Longmore, A.M.S., for permission to make use of this clinical material.

LOW SPINAL ANAESTHESIA DURING LABOUR IN CASES OF CARDIAC FAILURE

BY

HAROLD BURTON, B.M., B.Ch., D.R.C.O.G.

Resident Obstetrical Officer and Deputy Medical Superintendent,
Stoke-on-Trent Hospital

Most authorities are now of the opinion that it is not justifiable to perform a Caesarean section on a cardiac case merely for the sake of sterilizing the patient at the same time. If, therefore, normal labour is to be allowed in these cases, it is the aim of this paper to show that by far the safest method for it to take place is under low spinal anaesthesia.

It is generally accepted that the dangerous stage of labour in a cardiac case is the second. During this stage, with its attendant bearing-down and straining on the part of the patient, the heart is put to its severest trial, as can readily be observed in the labour ward. The patient is seen to become cyanosed and her pulse to falter during these bearing-down efforts. The method of anaesthesia here described depends essentially upon cutting out these bearing-down efforts while otherwise allowing labour to proceed normally. The essential stimulus to bearing-down is the pressure of the presenting part on the pelvic floor and perineum. The low spinal method anaesthetizes just these parts, and these only, and thus breaks the bearing-down reflex on the afferent side of the reflex arc.

The usual objection to the use of spinal anaesthesia for cardiac and other patients is that it causes the blood pressure to fall. This is true of routine spinal anaesthesia, but not of low spinal anaesthesia. A glance at the anatomy and physiology of the sympathetic system will explain this. The sympathetic outflow from the cord, which is chiefly responsible for the tone of the smaller vessels and therefore the blood pressure, comes from all the thoracic and the upper two lumbar segments. Any spinal anaesthetic, therefore, which acts below the second lumbar segment has no effect on the blood pressure. This was confirmed in all cases by taking routine blood-pressure readings at half-hourly intervals before and after the spinal injection. The use and technique of low spinal anaesthesia depend upon this fact.

The Method

The technique is simple. Heavy percaïne is used because it has been found that its effect is more lasting than that of other heavy spinal anaesthetics. The dose is 0.6 c.cm. The patient's back is prepared in the usual manner, and she is then sat up on the bed. The anaesthetic is given in the

ordinary way between the third and fourth lumbar vertebrae, and the patient is kept sitting up for at least ten minutes to enable the anaesthetic to fix. The anaesthetic drops down to the bottom of the spinal theca. The sacral nerves only are anaesthetized, and a saddleback area of anaesthesia is produced over the perineum.

The anaesthetic is given just before full dilatation of the os, so that when the presenting part is pressing on the perineum bearing-down will be obviated. It is noteworthy that the ordinary labour pains in the abdomen and back can still be felt by the patient. These pains, however, do not cause her to strain: they merely cause discomfort. If the dosage has been correct neither the abdominal walls nor the thighs will be affected.

In order to develop the technique fully, about a hundred normal cases were delivered by means of low spinal anaesthesia. About half of them delivered themselves spontaneously and almost painlessly, and the rest were delivered by a low forceps extraction without further anaesthetic up to as long as six hours after the low spinal anaesthetic had been given.

Even for a normal patient and labour this method has advantages—i.e., by allowing normal labour to proceed without any feeling of perineal distension. Women thus anaesthetized, if told to do so, can bear down by reason of their abdominal musculature being left intact. If a perineal repair or a forceps delivery is subsequently necessary it can be performed without any further anaesthetic within six hours. My aim, however, is not to discuss this mode of anaesthesia with reference to normal labour, because here, although rendering the labour easy and painless, it is open to the objection that it is an undue interference in a normal case. But this objection does not apply to cardiac cases. These patients, instead of suffering the shock of an abdominal section under local anaesthesia, can have a normal labour without any extra strain upon their heart.

Any case of longitudinal lie can be treated by this method. Naturally the patient should have been at rest and her heart compensated so far as is possible, with or without digitalis, before labour. The discomfort of the first-stage pains should be reduced by the use of morphine-scopolamine analgesia.

Illustrative Cases

Case 1.—Mrs. M. is an example of a vertex presentation. She had had a premature labour two years previously and was extremely anxious to have a living child with this pregnancy. She attended the ante-natal clinic on Jan. 18, 1943, when she was 22 weeks pregnant. She was dyspnoeic even at rest. Her apex beat was very irregular, varying between 70 and 150 a minute. The pulse showed many dropped beats. An electrocardiogram on Jan. 26 showed a grossly irregular action due to a nodal rhythm. The patient was brought into hospital and digitalis therapy started, but by the second day her apex beat had dropped to 40 and the digitalis was discontinued. It was decided, after consultation with Dr. Boyd, the consultant physician, to keep the patient at complete rest until normal labour began. She started having pains on May 18. Morphine and scopolamine were given during the first stage. Her blood pressure was 110/80; the pulse rate varied between 70 and 140, and was irregular. At this stage, when the os was almost fully dilated, a low spinal anaesthetic was given. The blood pressure remained constant at 120/80. The patient was delivered one hour later by low forceps. At no time during the labour was she distressed beyond feeling the pains of uterine contractions. The puerperium was uneventful.

Case 2.—Mrs. H., a primigravida aged 22. Breech presentation due July 13, 1942; sent into hospital with cardiac decompensation on July 2. She was a case of classical mitral stenosis with pre-systolic murmur. There was dyspnoea at the slightest exertion. She had had a haemoptysis for a week before admission. Pulse rate, 120 at rest. Complete rest was ordered and digitalis therapy was started immediately. After a week she was fairly well compensated, with a pulse rate between 70 and 80. Pains started at 3 a.m. on July 21, and she was kept under morphine and scopolamine. The blood pressure at this stage was 125/80. The os was almost fully dilated at 6.45 a.m. Heavy percaïne 0.6 c.cm. was given. The blood pressure remained constant. At 9.30 a.m. the breech was presenting. Episiotomy was performed and the child delivered normally. At no time was there the slightest distress.

Many other similar cases have been delivered by this method without any fatality. These patients are usually asked to attend a birth control clinic after discharge and to return later for

sterilization. This can then be performed when the heart has not the added burden of the placental circulation with which to cope.

One complication of the method must be mentioned. A spinal headache seems to occur much more frequently in pregnant than in non-pregnant patients. The headache often lasts for as long as a week. Several methods have been tried both to prevent and to relieve this spinal headache; but none of them is uniformly successful, and these methods are beyond the aims of this paper.

I wish to thank Mr. C. Gordon Lewis, F.R.C.S.Ed., medical superintendent, and Dr. J. Lindsay Boyd, consulting physician, of the Stoke-on-Trent Hospital, for their help and consideration.

EFFECT OF DIET ON THE CONCENTRATION OF CHOLESTEROL IN BLOOD AND BILE

BY

NANCY GOUGH, B.Sc.

(From the Clinical Laboratory, Royal Infirmary, Edinburgh)

It is widely believed that the level of cholesterol in the blood and bile is influenced by the intake of cholesterol in the food, and for this reason the diet of patients with disorders of the biliary system has commonly been restricted to food low in cholesterol. The following investigations suggest that this irksome restriction may be unnecessary, since the concentrations of cholesterol in the blood and in the bile do not appear to be significantly affected by the ingestion of comparatively large amounts of cholesterol.

Effect of High- and Low-cholesterol Diets on the Blood Cholesterol

Hospital patients whose metabolism was supposedly normal were fed on low-cholesterol diets containing about 300 mg. of cholesterol a day for a fortnight, and blood specimens were analysed for cholesterol at intervals of three days, all blood samples being taken at the same time of day. Then the cholesterol content of the diet was increased by the daily addition of 900 mg. of pure cholesterol, three eggs (approximately 1,100 mg. of pure cholesterol a day), or 50 g. of sheep's brain (approximately 2,170 mg. cholesterol a day), the cholesterol content of the blood again being determined at intervals of three days.

FIG. 1.—Relation between cholesterol content of diet and concentration of cholesterol in plasma. The low-cholesterol diet contained approximately 300 mg. cholesterol and the high-cholesterol diet approximately 2,170 mg. a day, given as 50 g. of brain.

Of 10 such cases in which the estimations were made by the colorimetric method of Myers and Wardell, 8 showed the plasma cholesterol unaffected by diet, while in 2 cases the plasma cholesterol was definitely raised by the addition of

900 mg. of cholesterol a day to the basic diet, and also the daily addition of three eggs. Of another 10 cases, in which the estimations were made by the *digitonin-precipitation* method of Okey, in no instance did a *marked* elevation of the plasma cholesterol. The accompanying graph shows a typical result in a normal person (Fig. 1).

Cholesterol Absorption

Experiments on the effect of a single dose of cholesterol on the blood cholesterol were carried out on four normal subjects who had been fasting for twelve hours before each experiment. The estimations were made by Okey's *digitonin-precipitation* method. A cholesterol-free, fat-free meal supplemented by 5 g. of pure cholesterol was given, and a blood cholesterol curve constructed over a period of six hours. The blood cholesterol curves did not differ significantly from those obtained from the same subjects when given the same meal without the added cholesterol. As it was thought possible that the absorption of crystalline cholesterol is dependent on the presence of adequate fat in the intestine, this experiment was repeated 50 g. of fat as margarine being added to the test meal. Again no significant difference was observed. Fig. 2 shows the result in the case of two of these subjects.

FIG. 2.—Plasma cholesterol curves over a period of six hours. A=Test-meal (cholesterol-free, fat-free). B=Test-meal + 5 g. cholesterol. C=Test-meal + 50 g. fat. D=Test-meal + 50 g. fat and 5 g. cholesterol.

The conclusion from these experiments appears to be that 5 g. of crystalline cholesterol by mouth has no effect in raising the free or esterified cholesterol in blood. Whether these findings can be explained by a failure in absorption of crystalline cholesterol, or by some mechanism whereby it is removed from the blood or altered into some compound not detected by the analytical method employed, is uncertain.

Effect of High- and Low-cholesterol Diets on the Cholesterol Content of the Bile

These experiments were carried out on 10 patients with biliary fistulae. The clinical condition of 4 of the patients did not permit the giving of experimental diets, and they were therefore kept on a light ward diet, which has a fairly constant low-cholesterol content of approximately 300 mg. a day. The remaining 6 patients were given a special low-cholesterol diet containing less than 300 mg. of cholesterol. After a period of two or three days they were given a diet with a high content of cholesterol, as the pure substance or as brain, for a further period of three days. Bile was collected from the fistula or alternate days. The cholesterol content of the bile was invariably very low immediately after the operation, but rose gradually, presumably as the liver damage lessened, although there was considerable day-to-day variation. This variation was most pronounced (10 mg. to 45 mg. per 100 c.cm.) in a case with severe hepatic damage (gross jaundice). There was also a great daily variation in the volume of bile which drained externally.

In human beings with a biliary fistula it is impossible to determine what proportion of the bile is draining externally and what is draining into the intestine via the common duct; hence no calculation can be made of the total secretion of bile

cholesterol. But it is possible to compare the concentration of cholesterol in a given sample of bile with the cholesterol ingested in the diet.

Of 10 patients with biliary fistulae, 1 showed a distinct rise in the bile cholesterol concentration on a diet containing a high content of cholesterol (about 2,000 mg., given as 50 g. of sheep's brain a day); 1 a rise when the high-cholesterol diet was first given, with a subsequent return to the original level (the patient still on the high-cholesterol diet); and 2 a fall in the cholesterol concentration of the bile on a low-cholesterol diet. In 6 no significant or sustained changes in the bile cholesterol concentration coincided with changes in the cholesterol content of the diet. The results in one of these six cases are shown in Fig. 3. The duration of these experiments was limited by the short period of time during which the fistulae remained open.

FIG. 3.—Concentration of cholesterol (free) in bile of a patient with biliary fistula. The low-cholesterol diet contained approximately 300 mg. a day, and the high-cholesterol diet 2 g. given as the pure substance.

To overcome the difficulty mentioned above with regard to determining the total output of cholesterol in the bile recourse must be had to operations on animals. Prof. Learmonth inserted a tube into the common duct of a dog so that all the bile drained externally. The animal remained in excellent condition for one month, the absence of bile in the intestine being compensated by giving 1 g. of sodium taurocholate by mouth every day. The total volume and the cholesterol concentration of the bile were measured daily; for the first three days insufficient bile was secreted for analysis, but thereafter it increased, although there was considerable fluctuation both in the volume and in the cholesterol content. After about ten days these became fairly constant (concentration of cholesterol in bile 13 to 14 mg. per 100 c.c.m., and total bile cholesterol excreted about 20 mg. a day). Approximately 2 g. of cholesterol was then fed in the form of 50 g. of sheep's brain, and there was an immediate rise in the bile cholesterol (27 mg. per 100 c.c.m. and total bile cholesterol 38 mg.), which was maintained for 48 hours; but subsequently both concentration and total output of cholesterol in the bile returned to the original level, although the high cholesterol content of the diet was maintained.

Conclusion

Further experimental work on animals is obviously required before any definite conclusion can be reached as to the effect of diet on the total output of bile and cholesterol, but the evidence of the foregoing experiments on human beings seems to indicate that there is no direct correlation between the intake of cholesterol and its level in the blood and bile. These observations give no support to the contention that foods rich in cholesterol should be prohibited in the diet of patients with cholecystitis and cholelithiasis. The exclusion of butter, fat, eggs, and liver from the diet of patients with diseases of the biliary tract is based essentially on the hypothesis that gallstones are formed from cholesterol, and that a reduction in the intake of cholesterol accordingly reduces the liability to

gall-stone formation. Such a low-fat, low-cholesterol diet is unphysiological because fat is the natural stimulant to biliary contraction and drainage, and has the further disadvantage of being unpalatable, monotonous, and low in fat-soluble vitamins.

My thanks are due to Prof. L. S. P. Davidson and Dr. C. P. Stewart, under whose direction this work was done, and to Prof. J. R. Learmonth, who carried out the necessary animal surgery. Part of the expenses were defrayed by a grant from the Medical Research Council to Prof. Davidson.

Medical Memoranda

Contramine for Herpes

Herpes is very prevalent in this locality and is often of great severity; in some cases the acute stage has lasted for months and the after-effects for years. Hence my satisfaction when I stumbled on a specific which provided a rapid cure of this painful malady. By means of this treatment, if given early, the acute pain is often relieved in a matter of hours, the vesicles disappear in a week or so without pitting, and there are no after-effects.

Some time ago, while attending an elderly lady for rheumatoid arthritis, I gave a course of injections of contramine. When visiting her to administer the second injection she complained of acute pain in the right supraorbital region. The next day I had an urgent summons, and found a very extensive herpes rash present. To my surprise this completely disappeared in five days. On the assumption that the contramine cured rather than caused the herpes, I have in the last twelve months treated 15 cases by this method.

The results may be summarized as follows: Average duration of pain before case diagnosable, 4 days; average time between irruption and injection, 16 hours; average duration of irruption, 7½ days. In a few cases among elderly patients of the residential class there was some neuritic pain for a further week after the skin was normal.

The efficacy of the treatment was most pronounced in those cases in which the injection was given within a few hours of the first appearance of the spots, especially in the pre-vesicular stage. The following cases may serve as examples, taken in more detail:

REPORTS OF CASES

Case 1.—On Sept. 5, 1942, a single lady aged 70 consulted me about an acute pain which she referred to the eye. On the following evening I received an urgent message to visit her, as she had fainted with the pain, which was of a spasmodic character. I then arranged with a consultant ophthalmic surgeon to see her the following afternoon. The next morning I witnessed an acute attack severe enough to make her pulseless. By this time I suspected an acute herpes, which was confirmed by the consultant in the afternoon. Contramine was then given, with the result that there was no further pain, nor did any rash develop, and apart from a few days' weakness the patient was well.

Case 2.—On Dec. 24, 1942, a man aged 76 complained of violent occipital neuritis, and two days after this a slight rash appeared from occiput to orbit. Contramine was given, and the vesicles never fully developed but formed dry scabs. This would undoubtedly have been a very severe case, but he was well in a fortnight.

Case 3.—A working man aged 52 complained of an increasingly severe pain in the chest and loss of sleep for two nights. His work was hard, and as it was essential he wished to carry on, but doubted whether he could. On examination an early shingles rash was found over the whole of the left chest. An injection was given, and two days later he reported that the pain had ceased entirely in four hours. All symptoms had gone in four days.

In five cases drawn from the working-class similar results were obtained—much better than in elderly, and wealthier, patients.

ITS USE IN CHICKEN-POX

I have reason to believe that the treatment is equally effective for chicken-pox. Of the three cases in which I have used it details of one may be of interest—the only early case.

A boy aged 16, living at a hostel for evacuees, most of whom had not had this complaint, had an attack with a severe onset, and was injected with contramine 12 hours after the appearance of the rash. On the third day, being quite well, he was allowed up, did gardening, and mixed with the other children. None of these were infected.

COMMENT

The injection intramuscularly of 1 c.c.m. (0.125 g.) of contramine (B.D.H.) gives a dramatic result in early cases of herpes, and is of great value in chicken-pox. In no case was pitting or

scarring of the skin visible after recovery, nor was there a long-continued irritation. In a few cases a second injection was given, especially if the first was given late and the rash was well developed.

Its use in chicken-pox, especially in young children, has not yet been investigated fully.

I should be interested to receive reports from other medical men who might be disposed to try this treatment.

Budleigh Salterton,

EWART S. HAWKES, M.B., Ch.B.

Vomiting Sickness in Jamaica

For some years now, beginning in the autumn and continuing through the winter, with the peak in January, a condition termed "vomiting sickness" for lack of a more appropriate name claims many lives of the people of Jamaica, especially the lower class. For some time the ackee, a local fruit, has been thought to be the source. Had it been so the population would have been greatly reduced, since it is a very cheap article of diet and eaten by all. Children eat even the uncooked fruit without any untoward results. The local authorities have done little, if anything, to probe the cause in spite of its yearly toll. Sometimes two, three, or even four children in the same household fall to this malady within a day or two. In many instances the attack is severe and causes fear and concern among the community. The recent outbreak was widespread and claimed many lives. The clinical features are dramatic and acute. The majority of fatal cases seldom last longer than a day, in some instances hours. The doctor is generally called when the condition is well on the way: in some cases the patient is dying. The history is usually "bad feeling" in the abdomen and epigastrium, anorexia, vomiting (sometimes bile-stained, sometimes glairy and rosy). Clinical signs are mainly restlessness without anxiety, dehydration, eyelids usually closed, contracted pupils which are finally dilated, rapid—sometimes full—pulse, slight increase of temperature. By this time the patient is often unconscious. Sometimes the vomiting follows a meal without any previous warning.

Varying clinical symptoms dominate the picture. These are exemplified in the following cases:

ILLUSTRATIVE CASES

Case 1.—A boy aged 12 "was well until the day before, when he did not have his dinner," and complained of pain (cutting and gripping) in the abdomen (chiefly in the umbilical and epigastric regions). He soon became unconscious, with locked jaws; there were periodical states of irritability and restlessness, and stiffness of some extensor muscles. He was dehydrated. Response to symptomatic treatment was good.

Case 2.—Boy 7 years old—apparently well "this morning"—had a sudden "bad feeling" in the abdomen and epigastrium, followed by vomiting and fits. He soon became unconscious and comatose, with stiff extensor muscles, marked opisthotonos, locked jaws, severe dehydration, rapid full pulse, and slightly increased temperature. Death occurred a few hours later.

Many other cases were observed in which abdominal symptoms were more pronounced than the above. In my opinion there are many factors which undoubtedly contribute to this "vomiting sickness." It may have had its origin in the previous dry season. The children are usually anaemic, poorly clad, in unhygienic surroundings, generally malnourished, and in some instances worm-infested. The high temperature in the summer, fresh fruits, green vegetables, etc., seem to tide them over till winter, when all these are absent; then the effects show themselves in "vomiting," "abdominal pain," etc.

The condition usually appears with malaise and abdominal pain. The port of entry seems to be in the epithelial lining of small intestine. Is it that the condition has brought about greater permeability of the epithelial cells due to the lack of certain constituents of the blood causing substances or toxin in the gut to be absorbed in the circulation; or is there actual damage of the cells themselves?

In the case of worms the multiple sites of attachment may be important. Is the abdominal pain peristaltic in nature? The general symptoms would suggest circulatory invasion of some form of toxin. Clinically, sometimes there are evidences of meningeal irritation, stimulation of the centres in the medulla—respiratory, vasomotor, vomiting, etc. What, then, is the composition of the toxin, sapotoxin, split-proteins, or bacteria concerned? The laboratory must decide.

From the above one could say that the following conditions contribute much to the cause of "vomiting sickness": (1) a certain lack of nutritional and vitamin requirements; (2) exposure to (and ? shock from) sudden variations in temperature; (3) toxæmia from a possible intestinal origin. These three conditions usually are experienced by a certain class of the population with a very poor economic background.

THE DYSENTERIES

The Dysenteric Disorders: The Diagnosis and Treatment of Dysentery, Sprue, Colitis and Other Diarrhoeas in General Practice. By Sir Philip Manson-Bahr, C.M.G., D.S.O., M.D., F.R.C.P. Second edition. (Pp. 629; Illustrated. 30s.) London: Cassell and Co. 1943.

The first edition of this book, published four years ago, has been widely read. It has supplied medical men with invaluable information on the diagnosis and treatment of those most troublesome intestinal infections which may be grouped together as the dysenteries, including sprue, colitis, and diarrhoea. Since the outbreak of the present war certain advances have been made, the most remarkable of which is the application of the sulphonamides in the form of sulphaguanidine to the treatment of bacillary dysentery, which in the last war was responsible for so much sickness and death among the troops. In this war it is perhaps safe to say that so far bacillary dysentery has played but a minor part compared with ravages in the last war. One would ask: Is this the result of a specific therapy or is it wholly or in part due to improvements in Army sanitation, or possibly to some change in the virulence of the causative organisms? Whatever may be the real explanation there is no doubt that bacillary dysentery still occurs, while acute cases of virulent Shiga infections are by no means uncommon. It is in the last that sulphaguanidine is of such value, for its immediate use in full dosage rapidly cuts short the disease in the majority of cases. The use of this drug is fully discussed by the author, this section being the most valuable addition to the second edition of his book.

The author's development of his views on the nature of sprue as a complex nutritional disorder has necessitated a new chapter on pellagra, which serves as an introduction to a section on the steatorrhoeas. Another specific remedy, already noted in the first edition, is atebirin as an almost certain cure for giardiasis, that rather mysterious infection of the upper intestinal tract. Further evidence of its activity has accumulated, and this has been duly recognized in the new edition. In several other minor respects the book has been modified but its general arrangement is the same and it still retains its high position as the standard work of reference on the disorders with which it deals.

DERMATOLOGY

Diseases of the Skin. By Oliver S. Ormsby, M.D., and Hamilton Montgomery, M.D. Sixth edition, thoroughly revised. (Pp. 1,360; Illustrated. 70s.) London: Henry Kimpton.

This book maintains in its newest edition its place as one of the leading American treatises on dermatology. Only a few years have elapsed since the fifth edition appeared, but in order to combine modernity of outlook with economy of print the authors "have regrouped a large number of diseases, added two new classes, eliminated much material rendered obsolete through recent discoveries, added twenty-two diseases not previously included, and rewritten the accounts of many others." We quote from the preface. Certainly this is a remarkably complete handbook of dermatology, but while rare diseases or museum pieces receive mention the common cutaneous afflictions with which the practising doctor is chiefly concerned are given space which is proportionate to their greater importance. For example, there is a very good chapter on cutaneous syphilis and its treatment, including a discussion of the comparatively new method known as the massive five-day intravenous drip. The drug used for this purpose was at first neoarsphenamine (American for neosalvarsan), but this was found to be less satisfactory than mapharsen, and is now always substituted for the older preparation. In circumstances the advantage of compressing the whole of the necessary and adequate treatment for syphilis into five days is obvious, though it is not every patient who would tolerate an intravenous drip into the vein for ten to twelve days for five successive days. It is not entirely without interest that in 1,600 cases studied by the U.S.A. Public Health Service there were five deaths—nearly 1 in 300.

There is a full discussion on eczema and the various forms of ringworm, an infection which has recently assumed so much importance among eruptions on the hands and feet. The authors are perhaps most deeply interested in neoplasms, and the chapter devoted to this important subject is very interesting and full. They employ a term which is new to us—"lymphoblastoma"—and they use it to include mycosis fungoides, various types of leukaemia cutis, Hodgkin's disease, and lymphosarcoma of the skin. All these conditions have been long thought to be pathogenetically related, even though their exact connexions may not yet have been worked out, and it is convenient to have a single term to comprehend them all.

In short it may be said that this is a very good textbook of dermatology well worthy of the medical school of Chicago and of the Mayo Foundation from which it has sprung. It is well illustrated with excellent photographs, and the only criticism of its format we make is that it would be easier to handle if it were divided into two volumes.

REVIEW OF PHYSIOLOGY

Annual Review of Physiology. Volume V. Editor, James Murray Luck; Associate Editor, Victor E. Hall. (Pp. 613. 55.00 or 31s. 6d.) California: American Physiological Society and Annual Reviews, Inc.; London: H. K. Lewis and Co. 1943.

Several of the reviews in this excellent publication, the standard of which is well sustained by the present edition, will be of use to clinical investigators as well as to physiologists. It need hardly be said that physiologists will find the volume as valuable as its predecessors have been.

Reviews which will be valuable for reference in fields in which it is not easy to collect information are the ones on "Physiological and Pathological Effects of Ultraviolet Radiation," by H. F. Blum; "Physiological Aspects of Genetics," by C. V. Taylor; "Visceral Functions of the Nervous System," by H. W. Magoun; "Temperature Regulation," by L. P. Herrington and A. P. Gagge; "Metabolic Functions of the Endocrine System," by B. A. Houssay and V. Deulofeu; "Physiology of Mammalian Semen," by J. MacLeod; "Endocrinology of Reproduction," by C. A. Pfeiffer; "Physiological Psychology," by N. Cameron and H. F. Harlow; and "Biological Assay," by C. I. Bliss and M. Cattell. The last-named is a particularly critical article, which deals with a topic of growing importance; it is well digested and full of information.

Other articles of general value to the physiologist are the ones on "Physical Properties of Protoplasm," by C. V. Taylor; "Developmental Physiology," by W. F. Windle; "Physiology of Bone," by F. C. McLean; "Energy Metabolism," by E. B. Forbes and L. Voris; "The Respiratory System," by C. L. Gemmill; "Muscle," by E. Fischer; "The Digestive System," by R. C. Herrin; "Blood," by H. D. Bruner; "The Lymphatic System," by P. D. McMaster; "Heart," by F. D. Johnston and F. N. Wilson; "Nerve and Synaptic Transmission," by B. Renshaw; "Liver and Bile," by J. L. Bollman; and "Sense Organs," by H. Davis and S. H. Bartley.

The subjects of temperature regulation, respiration, sense organs, heart, and biological assay are now much to the fore, and workers in many fields will find those contributions useful. Three of the articles intended have, for one reason or another, had to be omitted; in view of the present situation this is a surprisingly small number. But, as the editors say, "What a flood of discovery will be revealed in the first few years of the post-war world when the present barriers to intellectual co-operation melt away!" Yes, indeed.

WAR WOUNDS AND INJURIES

War Wounds and Injuries. Edited by R. Maingot, M.R.C.S., E. G. Steinger, M.S., F.R.C.S., and Ernest Fletcher, M.B., M.R.C.P. With foreword by Lord Horder. Second edition. (Pp. 499; illustrated. 35s.) London: Edward Arnold, 1943.

The second edition of this compilation on war injuries has been largely reconstructed. Two new editors share the responsibility and many new contributors have been drawn in. The work now gives a fair representation of the views on war surgery at home. It is noticeable that none of the contributors have had active experience in the Middle East. The articles on peripheral nerve injuries by Highet and that on the chest by Tudor Edwards are perhaps of most outstanding value. All

the other articles offer sound advice by those who have had practical experience of the subjects dealt with. In the section on burns the treatment described, though advised by the Navy, is not in line with the current ideas of the Army and of the Air Force. The book is well produced, and the illustrations, which are mainly photographic, show fair detail. Both the size and price of this edition have been approximately doubled.

Notes on Books

The Advancement of Science, No. 8, just published at 5s., completes the second volume of this, the official publication of the British Association for the Advancement of Science (Burlington House, London, W.). It was established by the Association shortly before the war as a quarterly, of which four parts made a yearly volume. In wartime the quarterly issue was found inexpedient, and the volume now completed covers the period since September, 1941, when the Association's Division for the Social and International Relations of Science held its conference on Science and World Order. That conference directed attention to a whole series of post-war problems bearing upon the impacts of science on society. Of particular interest in the present series of papers is the address on the Public Understanding of Science by Sir Henry Dale given on March 20, 1943, and Sir Richard Gregory's address on Science and the Press given on March 21.

A sixth edition of Prof. F. J. BROWNE'S *Advice to the Expectant Mother on the Care of her Health and that of her Child*, which first appeared in 1926, has been published by E. and S. Livingstone of Edinburgh at 6d., plus 21d. postage. The booklet has been revised throughout, and there is a new short chapter on pregnancy and labour to help the expectant mother to co-operate with midwife or doctor.

Dr. W. GORDON SEARS, medical superintendent of the Mile End Hospital, has prepared a small work *Materia Medica for Nurses*, his object being to link up drugs and therapeutics with physiology and to give enough information to be useful to the nurse for reference after passing her examinations. Some stress is laid on therapeutic procedures, signs of overdosage, and points which the nurse can observe or has to carry out for herself. The guidance of a competent teacher is presupposed throughout the text, which is clearly written and practical in range. Edward Arnold and Co. publish the book at 5s.

Save the Children of Belgium is the title of an 8-page leaflet in which M. Emile Cammaerts (3, Hillside Road, Radlett, Herts) has collected available information on the food and health conditions (based on medical reports) of the children of Belgium. He also describes the scheme for restricted medical relief proposed by the Famine Relief Committee. Much of this material has already appeared in these columns, but brought together it makes out (from the medical point of view) an unanswerable case for sending a small monthly shipment of food concentrates to that stricken country.

Preparations and Appliances

HEAD TERMINALS FOR CONVULSIVE ELECTROTHERAPY

Dr. E. FRETSON SKINNER (Sheffield) writes: One of the minor difficulties of convulsive electrotherapy is that of easy application and removal of the head terminals. The usual method of a rubber band and pads is awkward of adjustment and time-consuming if large numbers of cases are to be dealt with, while the heavy caliper type of headpiece supplied by one firm is too heavy and cumbersome as well as alarming to the patient. For two years now I have been using a very simple home-made piece of apparatus, consisting of an adaptation of wireless head-phones in which the microphones are replaced by solid disks of fibre, into one face of which a metal plate is let and connected by a screw terminal going through to the other side of the disk with the necessary leads. The springs on the head-phones have been reinforced by two steel strip springs bound to the phone-springs with elastoplast strapping. The whole apparatus can be made for a few shillings and is extremely handy, as it can be slipped on to the head and removed in a moment.

Joseph E. Smadel (*J. clin. Invest.*, 1943, 22, 57) found that 10 out of 45 sporadic cases of atypical pneumonia were caused by infection with strains of the virus of psittacosis. In no instance was the virus of lymphocytic choriomeningitis associated with the illness of individuals in the group, and in only two instances was influenza virus suspected as a possible aetiological agent.

MISLEADING MALARIA

BY

Sir MALCOLM WATSON, M.D., F.R.F.P.&S.

In view of the danger from malaria to our Armies operating in Southern Europe and other malarial areas Capt. Birks's paper, "Symptomatology of Malaria," in the issue of the *Journal* of June 26 is a timely warning of some of the ways in which malaria attacks without causing febrile symptoms, and so may mislead the physician. There are other ways in which "malaria kills, not in the hot blood of a fever, but in cold blood, masquerading as some non-febrile disease." The following is a summary of a paper, "Some Clinical Features of Quartan Malaria," by myself, which appeared in the *Malayan Medical Journal* in 1904 and the *Indian Medical Gazette* in 1905.

Quartan malaria rarely kills as a febrile disease, and is especially suitable for the study of chronic malaria.

In 18% of 66 cases pyrexia was absent
In 18% " 66 " " occurred at long intervals
In 32% " 83 " oedema was a prominent feature
In 18% " 83 " " overshadowed all other features

In some cases the combination of normal temperature, dense albumin in the urine, with blood and tube casts, had led to a diagnosis of acute nephritis until the discovery of quartan malaria parasites. This condition is much less common with the other parasites. In 20 of 83 cases it was diarrhoea or dysentery which brought the patient into hospital, and there was no complaint of fever. In 5 out of 83 cases there were abscesses—some large, multiple, and painless. In nearly all cases cough was common; in some there was severe bronchitis. It was the failure of an ulcer to heal that first put me on to the track of afebrile quartan malaria, and thence to afebrile malaria generally.

In an article entitled "Rare Nervous Symptoms produced by Malaria" (Watson, 1908) I drew attention to epileptiform attacks in B.T. malaria and paralysis of the sixth nerve, presumably the early symptom of malaria coma.

In a "Note on the Parasites of a Case of Malignant Malaria, with a Discussion of the Development of the Crescent" (Watson, 1903) I wrote, describing a peripheral blood film: "In many places groups of as many as 30 almost fully developed parasites were counted, reminding one of what is occasionally seen in cerebral and other capillaries. This suggested that red corpuscles infected by M.T. parasites develop adhesiveness, which accounts for the blockage of capillaries, and might explain the 'generalized disease of arterioles and capillaries' suggested by Capt. Birks as the cause of the symptoms in his cases.

The full significance of unrecognized malaria I did not realize until, as a result of antimalaria work begun in 1901, the following figures were compiled:

Number of Deaths in Kland and Port Swettenham corrected for Deaths Occurring in Hospital

	1900	1901	1902	1903
Fever	259	368	59	46
Other diseases ..	215	214	85	69
Totals	474	582	144	115

Further experience of successful antimalaria work has consistently shown a decrease in "other diseases" such as diarrhoea, dysentery, convulsions, and anaemia.

Quinine Injections

Normally, quinine by mouth is sufficient, but there are many exceptions to the rule. A medical friend staying with me relapsed from B.T. malaria. His tongue became dry. He was given quin. bihydrochlor. 7 gr. t.i.d. At the end of 48 hours he still had fever and parasites. Meyer's reagent showed no quinine in the urine. Intramuscular injections produced the desired result.

When quinine is injected intramuscularly it is safer to limit the amount injected in one place to 5 gr., and less painful to the patient. In 1933 I carried out a series of experiments with guinea-pigs and rabbits. As the dose of quinine bihydrochloride was raised from 1 gr. to 5 gr. the oedema and redness, seen on cutting into the site of the injection 48 hours later,

increased. On injecting 8 gr. extensive sloughing was observed. A patient came to me with both thighs puckered in different places. She had had a course of injections.

An injection of morphine, with a good sleep, is appreciated by the patient after sleepless nights and severe headache. Doctors themselves will find if they contract malaria.

Hyperpyrexia

When I first went to the Tropics I wondered how I would treat hyperpyrexia in malaria in the absence of ice. True that the temperature in B.T. malaria often rises to 104° and over, but I have never seen hyperpyrexia endanger a patient's life. The late Dr. C. W. Daniels, who had a long experience of malaria, both clinical and pathological, told me that this was his experience also in uncomplicated malaria. I thought the textbooks had inherited the heading from the microscope days, when typhomalarial fever was a common diagnosis. When I did meet hyperpyrexia in other diseases it was easily controlled by sponging with or pouring on water at a temperature about 80° F., to the great comfort of the patient.

SCOTLAND'S HEALTH

It says much for the work of the Ministry of Food that the Department of Health for Scotland in the fourth year of its work can place "the nutritional basis of food rationing" second only to the Department's own efforts in the factor responsible for the satisfactory state of the public health during 1942. Other contributing causes are stated in the annual summary report of the Department to be the increased employment and purchasing power of the working classes (though it is difficult to see how the latter plays a part when consumer goods are so limited) and the mild winter. As in England, however, there was no absence of health problems.

The incidence of tuberculosis was higher than it has been for some years—9,126 notifications, as against 8,302 in 1941 and 7,498 in 1938. Deaths were 80 per 100,000 of the population, as compared with 83 in 1941 and 69 in 1938. New cases of venereal diseases treated at Scottish centres numbered 10,999, compared with 10,531 in 1941 and 6,929 in 1939; there were more cases of syphilis and fewer of gonorrhoea. The report states that it is too early yet to judge the effect of Regulation 33B, but "common" sources of infection named so far have been few. The only other disease the increase in which can be attributed to war conditions is cerebrospinal fever. The number of confirmed cases (1,621) was 247 fewer than in 1941, but it was still over five times greater than the figure for 1938 and 1939.

The infant mortality rate, which was 69.3 for the year under review, has only once been lower, and that was in 1939, when the rate was 68.5. The report of the subcommittee of the Department which has been examining this problem is expected shortly. Scotland now has 99 wartime nurseries for 4,353 children, as compared with 29 for 1,180 a year ago. About 1,000,000 people were vaccinated in Scotland during the small-pox outbreaks last year; eight deaths were recorded in each of the three principal centres of outbreak—Glasgow, Fife, and Edinburgh. References are made in the report to the successful "Clyde Basin Experiment," under which 3,758 workers have been medically examined, many by the specialist service provided, and 1,523 admitted to hospitals or convalescent homes.

On the subject of the Beveridge report there is the following comment: "The adoption of the proposals would involve the supersession of the present scheme of National Health Insurance, with its segregation of the insured population in financially separate approved societies and branches, charged with the administration of sickness, disablement, and maternity benefits. The present restriction of medical benefit to insured persons and the administration of this benefit by insurance committees would likewise disappear." The Department, like the Ministry of Health in England, is discussing the future of the medical services with representatives of doctors, hospitals, and local authorities. The Committee on Post-war Hospital Problems (chairman, Sir Hector Heitherington) is expected to report at an early date, and hospital surveys, which should be completed in the autumn, are being carried out by special commissioners.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 25 1943

PNEUMOKONIOSIS AND WORKING CONDITIONS IN COAL MINES

A twofold problem confronted the Medical Research Council's Committee on Industrial Pulmonary Disease when it undertook to investigate chronic disease of the lungs of South Wales coal-miners. First, the nature of the disease and its occupational and geographical distribution in the South Wales coalfield had to be examined. Secondly, the effect of environment in the causation of the disease had to be determined, and preventive measures devised on this basis. The first part of the problem was medical and pathological; the second part required the study of the many factors in the working environment. A report on the first was published a year ago.¹ A second volume, containing reports by the teams who have been studying the environmental aspects of the problem, has now been issued.²

It was shown in the first report that the incidence of pulmonary abnormality, as judged by x-ray evidence, was related to the rank of coal being mined. The incidence and severity of the disease were greatest among those working at the coal face of anthracite mines, least in colliers employed in bituminous coal mines, and intermediate among those who mined steam coal. Within the anthracite area there were distinct local variations in incidence. That the chronic lung disease of South Wales coal-miners is due to the inhalation of "dust was clearly shown. The committee recommended that it should be recognized as an industrial disease under the name "pneumokoniosis of coal-workers," and that the diagnostic criteria required for purposes of compensation should be extended to include the various lung changes of this disease discovered by the medical survey. The Workmen's Compensation Act, 1943, gives power to make compensation schemes on the basis of those recommendations.

The second report considers fully the concentration of dust in the air breathed by the collier at the coal face, the size of the dust particles and their nature, the composition and characteristics of the strata from which the dust is derived, the concentration in the air of the nitrous fumes from shot-firing, and the temperature and humidity of the air to which the miner is exposed when at work and during his journey to the surface at the end of the shift. As such an investigation was laborious it was not possible to study in detail the working conditions in all the mines included in the medical survey. A difficulty in an investigation of this sort is that conditions of work tend to change with the passage of time. For example, since the last war machine-mining has increased greatly in Britain. Pneumokoniosis may take years to develop, and the disease manifest now may have begun in the circumstances prevailing ten, twenty, or more years ago. An attempt was therefore made to select for investigation mines in which conditions had not changed much.

Mass concentrations of air-borne dust in a number of collieries in the anthracite, steam coal, and bituminous coal areas were determined by Briscoe and his colleagues. Their samples were later ignited and the ash was weighed ;

the mass concentrations of the whole dust and of the ash, and the percentage of ash in the dust, were thus ascertained. The incidence of pulmonary x-ray abnormalities was found to be significantly and positively correlated with the average ash concentration. High ash concentrations tend to be associated with high concentrations of the whole dust, and this probably accounts for the apparent correlation between the incidence of lung trouble and the total dust concentration. The incidence of pneumokoniosis does not appear to be related to the ash percentage *per se*. The findings of Briscoe and his team may be compared with Belt's conclusion in the earlier report that the dust-reticulation and fibrosis were due to silica, whether as free silica or silicates, rather than to coal. Estimations of the number and size of the air-borne dust particles by Bedford and Warner pointed to an association between the incidence of pneumokoniosis and the mass concentration of particles, particularly those below 5 microns in size, both of coal and of mineral matter other than coal. This evidence is quantitative and confirms that the incidence of lung disease is related to the amount of dust inhaled. Chemical and x-ray diffraction analyses of the mineral matter of the coal seams, of the air-borne dusts at the coal face, and of certain screened fractions of run-of-mine coal, were made by Hicks and Nagelschmidt. The dusts and screened fractions were all closely alike. The proportions of quartz in the rocks and air-borne dusts vary, but there is no clear relation to rank of coal or to incidence of pneumokoniosis, except that in the anthracite area the dusts generally have more quartz in the mines in which the incidence of lung disease is high than in those in which it is low. On an average, in all the mines the proportion of quartz in the dusts is 2%. Petrological examinations of the rock strata overlying the coal in different mines, made by Brammall and Leech, reveal a contrast between the shales in the anthracite and bituminous coal areas. Owing to the effects of compaction and metamorphism there are in the anthracite area an increase in the content of secondary quartz and mica, and a differentiation in the ground mass, or ultimate cement substance, of the shale. Hydrated ferric oxide and alumina, both of which depress the solubility of silica, are less evident in the shales of the anthracite area than in those of the bituminous area. Whether directly or indirectly, the incidence of pneumokoniosis appears to be associated with these geological changes brought about by pressure.

Although the lung disease of the coal-face workers differed in certain respects from the silicosis resulting from exposure to dust containing a very high proportion of quartz, that of the anthracite colliers was generally believed to arise from the inhalation of dust. Yet some held that exposure to dust was of secondary importance. Access to anthracite mines is usually by a slant driven in from the surface, not by a vertical shaft, and men are conveyed to and from work in spake trains. Bronchitis from chill during spake-riding was thought to facilitate the adverse effect on the lung of the air-borne dust at the coal face. Miners attributed the disease mostly to the irritant effect of the nitrous fumes due to shot-firing. The thermal conditions in seven of the mines were examined by Bedford and Warner. It appears that the incidence of lung trouble is influenced neither by the temperature nor by the humidity of the air at the coal face. As the miners ride in spake trains from workings to the surface they chill down, and there may be some association between this and the incidence of pneumokoniosis. But spake-riding seems at most to be but a contributory factor. As to nitrous fumes, Graham and Runnicles show that the average concentration liberated during shot-firing rarely exceeds 6 parts per million by volume in samples taken during the period of a shift, or 4 parts per million over a 24-hour period. Although no direct relation can be found

¹ British Medical Journal, 1942, 9, 43.² M.R.C. Spec. Rep. Ser., No. 244, London, 1943.

between the concentration of nitrous fumes and the incidence of lung disease, it is prudent to regard low concentrations of these fumes as a possible contributory factor. Relegation of shot-firing to a non-coal-getting shift would reduce exposure to fumes, and also the risk of exposure to exceptionally high concentrations of dust.

American workers have shown that dust concentrations can be reduced a good deal when all hewn material, coal or rock, is copiously sprayed with water before it is shovelled or otherwise handled. There are practical objections to the excessive use of water at the coal face, but spraying the hewn material with modest quantities of water from A.R.P. stirrup pumps has been shown by Bedford and Warner to be highly effective. High standards of maximum permissible dustiness cannot yet be laid down, but Bedford and Warner put forward standards which, the committee agrees, might well be taken as the target for to-day. It is suggested that minerals other than coal should not exceed 1 mg. per cubic metre, and coal 10 mg. per cubic metre, both these figures referring to particles 5 microns or less in size (larger particles are probably of relatively little pathogenic importance). Such concentrations cannot be measured directly by the ordinary gravimetric methods, but they can be estimated from the numerical concentrations of dust particles. With the thermal precipitator—an inconvenient instrument for routine work—as the sampling instrument the mass concentrations named above represent 60 particles of minerals other than coal and 700 particles of coal per c.cm., all particles below 1 micron in size being ignored. Various methods of dust sampling give widely divergent results, and before other instruments can be used to apply the suggested standards, study of the comparative sampling efficiencies of the instruments under actual mining conditions will be necessary. This work should be carried out without delay.

The apparent relation between incidence of pneumokoniosis and dust concentration, even in the bituminous mines of South Wales, makes one wonder what will be the effect of the widespread adoption of mechanized methods of mining, for some of the mechanical devices employed produce much dust. High dust concentrations have been reported in mines in other British coalfields. Actuated mainly by the desire to prevent coal-dust explosions, mining engineers have for some time been testing and applying various methods of dust reduction at loading points and other specially dusty localities. The findings of this report should be a stimulus to increased activity in that direction. Despite the large amount of work recorded in this symposium, the Committee on Industrial Pulmonary Disease has been unable to draw final conclusions on the causation of the pneumokoniosis or the differences in incidence observed in the South Wales coalfield. For some reason the dust of anthracite mines is more dangerous than that of bituminous mines, and a similar state of affairs exists in the U.S.A. and the U.S.S.R. The difference may lie in the quantity of dust or in its character, or both factors may be involved. The work now reported gives little support to the view that quartz is the main hazard, yet it does not make it possible entirely to exclude the quartz theory. Animal experiments still in progress may help to resolve this point. But whatever may be the ultimate reason for the greater danger of the dust in anthracite mines, a reduction in the amount of dust breathed by the miner is the one immediate measure which is likely to diminish the incidence of pneumokoniosis. To this end the committee advocates: (1) the maintenance of adequate ventilation; (2) the systematic use of water at the coal face to prevent the dispersion of dust; (3) the allaying of dust in roadways and at loading points; (4) reduction of shot-firing to a minimum, and the firing of shots when the fewest men are

exposed; (5) the relegation of all the processes of ripping to a back-shift. A further recommendation is that suitable means to prevent chill should be used during special journeys.

A STIRRUP CUP FOR THE PANZERS

No pharmacological innovation is so likely to catch the popular imagination as that which claims, in the words of Macbeth, "to raze out the written troubles of the brain" and this explains the stir caused by amphetamine in 19 years immediately before the war. On the Continent a substance known as "pervitin" became as popular as as much abused. Pervitin, or *d*-desoxyephedrine hydrochloride, the properties of which have recently been reviewed by Ivy and Goetzl,¹ is of special interest because it is apparently being used by the German armed Forces. This substance, marketed as methedrine in this country related to ephedrine and amphetamine, and in its pharmacological properties closely resembles the latter.

Its topical interest derives from the fact that, like amphetamine, desoxyephedrine causes a temporary increase in efficiency and initiative, with elation, lessened fatigue, an increased ability to concentrate. This may lead to irritability and sleeplessness, and, as with amphetamine, prolonged medication has a dwindling effect because of accumulation of the need to rest. So far as intelligence tests are concerned, Jacobsen and his co-workers² found that these substances increased the speed of work without changing its accuracy, and there seemed little difference between amphetamine and desoxyephedrine. Although published data on the effect of desoxyephedrine on physical performance are inadequate, it is probable that the drug, by lessening the sense of fatigue, increases output at expense of physical reserves. It will not, therefore, increase the total work capacity over a long period of time, the same of the German workers suggest that the depressive effects of fatigue can be counteracted for about two weeks. Its use has been recommended for such persons as engine drivers and night watchmen, as well as for the personnel of armoured units. It has also been used for raising the morale of patients after operation or in the last stages of chronic or malignant disease. Almost every German clinician with experience of the drug values it in this connexion for it seems to counteract the depression caused by morphine without impairing its analgesic properties.

The therapeutic dose recommended is 3 to 6 mg. by mouth; the optimal dose is nearer 9 mg., but side-effects may be experienced at this level. The German authorities claim; though their evidence is not well supported, that desoxyephedrine is superior to amphetamine because the difference between the therapeutic and toxic dose is greater. This explains their concentration on this particular compound. The dextrorotatory form is very much more active than the laevorotatory, and in both animal and human experience *d*-desoxyephedrine hydrochloride is slightly

¹ *War Medicine*, 1943, 3, 60.

more active than amphetamine sulphate, weight for weight. No deaths or serious intoxication have been reported, even with a dose as high as 200 mg.; this, however, will cause excitement, sleeplessness, mydriasis, nausea, vomiting, tachycardia, and a rise in blood pressure. No habit formation or addiction has been observed in the strict sense of the word; tolerance to the psychological effect is readily acquired, as with amphetamine. Various authors have suggested that the development of tolerance in patients of weak character may lead to increased and protracted medication to stave off for as long as possible the accumulated fatigue; for on withdrawal of the drug after a large increase of the dosage the patient may sleep for several days. The dangers of this drug are therefore the same as those of amphetamine, in that stiffening of the dose leads to undesirable cardiovascular and metabolic reactions. The German Government placed it under the narcotic law in 1941. The contraindications to its use include cardiovascular disease, thyrotoxicosis, and insomnia.

Desoxyephedrine has also been tried in nearly every condition for which amphetamine is used. As an analeptic or stimulant in narcosis it has much the same effect as amphetamine; but both drugs are inferior to picROTOXIN in barbiturate poisoning, and their general use is not recommended in the absence of further evidence. Dodd and Prescott⁴ have compared desoxyephedrine with other pressor agents in a series of 54 surgical operations. They found that with 10 to 20 mg. intravenously or 15 to 30 mg. intramuscularly there was a very satisfactory return of the blood pressure to normal, maintained over several hours. Desoxyephedrine was thought to be more efficient than even pholedrine or neosynephrin. Animal experiments have shown that in common with many other sympathomimetic agents desoxyephedrine causes tachyphylaxis (subsequent injections causing a smaller rise in blood pressure than the first one); this will certainly not exclude its use over a limited period of time, but it is well to bear the phenomenon in mind. It may be argued that the drug is contraindicated in surgery because its analeptic action may lead to the use of more anaesthetic; certainly the dose used by Dodd and Prescott would be greater than that desirable for an unanaesthetized patient. It is hoped that further experience will show whether these disadvantages are theoretical rather than practical.

CHEST SURGERY FILM

The British Council's film "Surgery in Chest Disease" had a special showing in London last week at the Curzon Cinema. It is the first of a series of medical films to be made for the Council. They are intended primarily for oversea medical audiences, and the choice of subjects and the planning of individual films have been undertaken by the medical department of the British Council, with the advice of a medical subcommittee formed for the purpose, and with the close collaboration of the Council's film department. In the various stages of planning the advice of a committee of chest surgeons, and of other individual medical experts, has been freely sought and taken. Most of the film was made in London at the Brompton Hospital. Apart from the expert advice which has gone into the preparation of the script, full collaboration of the staff of the hospital was secured in the actual shooting of the film, though extraordinary inconveniences were so caused. The purpose of the film, as explained to a deeply appreciative audience by Surgeon Rear-Admiral Gordon-Taylor on Sept. 14, is to indicate the scope and progress of chest

surgery and collateral services in Britain. The film opens with sequences showing a mass radiography survey of industrial workers. Then a radiologist is shown examining the miniature x-ray pictures projected on the screen. One of them is suggestive of disease of the lung, and the patient is referred to the chest hospital, where a full-size radiograph is made and he is examined by a physician. The findings point to cancer of the lung. The patient is next admitted to hospital. At this point a number of sequences depict other patients in various stages of treatment and explain the rationale of the procedures. The story of the original patient is then taken up again, and he is shown undergoing confirmatory diagnostic procedures and later having special breathing exercises to make him fit for removal of the affected lung. The theatre sequences depict all the important stages in the operation, which are seen with far greater clarity than would have been possible by standing at the surgeon's side. Interposed with these shots are diagrams explaining the anatomical relationships of the parts seen. The pre-operative procedures, the form of anaesthesia employed (administration of a volatile anaesthetic through a tube in the bronchus of the healthy lung), and auxiliary measures, such as drip blood transfusion during the operation, receive attention. After suture of the operative wound the patient is wheeled back to the ward, still receiving the transfusion and also oxygen. Stages in recovery are indicated in later sequences, including the treatment of a post-operative effusion. The patient is then shown at a later stage convalescing at a hospital in the country, where special rehabilitation measures not only aid his recovery medically but retrain him for his old job. In the final pictures he is seen being examined by the surgeon who operated upon him, who tells him that he is now fit to return to work.

The main case depicted in "Surgery in Chest Disease" illustrates a striking advance in surgical practice. Ten years ago a diagnosis of cancer of the lung was a death warrant from which there was no escape. To-day suitable cases can be cured and restored to full working capacity by surgery, though the operative risk is still great. Further, the film as a whole illustrates the growing importance of special techniques and of team work in modern medicine. Surgeons, physicians, anaesthetists, radiologists, pathologists, resident medical staff, sisters and nurses, physiotherapists and hospital almoners—all play an essential part in a complex series of processes which result in the saving of a life. The actual operation takes its logical place among a series of other special measures which precede and follow it, and which are essential to its success. Full marks must be given to everyone who helped in producing this masterly film—including the patient.

THE STOMACH AT WORK

Of late, interest in test meals has been waning, and this probably because but little return comes from this tedious procedure. Yet analysis of the gastric secretion may throw some light on gastric physiology in the individual patient. S. Wolf and H. G. Wolff,¹ for example, have been able to observe simultaneously changes in motor activity, vascularity, and secretion in the stomach of a patient with a permanent gastric fistula resulting from an operation performed nearly forty years earlier because of a benign stricture of the oesophagus. In the fasting stomach they found that the phase of active contractions was accompanied by heightened vascularity of the mucosa and an increased rate of production of acid. The blushing of the mucosa was found to be proportional to the increase in blood flow as determined by a thermal gradientometer. After the

⁴ *British Medical Journal*, 1943, 1, 345.

¹ *Amer. J. Physiol.*, 1943, 118, 309.

subcutaneous injection of histamine or the intragastric administration of alcohol or beef bouillon there was invariably an increase of vascularity and acid secretion. While active contractions did not occur unless the mucosa was red, intensified hyperaemia and high acid output were not always associated with increase in gastric motility—a finding in conformity with the results of W. F. Anderson.² Much work is required from the muscle and secreting cells of the stomach during periods of activity, and there is little doubt that the enhanced blood flow is necessary for the supply of extra oxygen and energy-yielding material. On the other hand, cellular activity is probably not the only cause of vasodilatation. Thus, Kuntz and Hazelwood³ found that applying warmth to the abdominal wall led to a vasodilatation in the serous coat of the small intestine. Of much interest to the clinician are the suggestions put forward as a result of these investigations. When a large volume of juice with a high titratable acidity is obtained from an unobstructed stomach, it may be deduced that there is an efficient blood flow through the mucosa and that motility is low. On the other hand, a small volume of juice of high acidity indicates hyperaemia of the mucosa with vigorous gastric contractions. Juice of low acidity, especially when of small volume, is very suggestive of a poor blood flow and a quiescent stomach. It is tempting to go a stage further and offer suggestions for treatment. Enough, however, has been said to renew interest in the performance of test meals and, it may be, in the evaluation of gastric tonics and sedatives.

ABSENTEEISM AMONG WOMEN WORKERS

In a report issued by the Industrial Health Research Board,⁴ S. Wyatt, R. Marriott, and D. E. R. Hughes describe the results of observations made at two Royal Ordnance factories, one of which, Factory A, is five times larger than Factory B and is situated in an isolated position. The samples of women investigated number 819 and 495 respectively, and they were tested over a six-weeks period in the summer of 1942. All the women were on a three-shift system, and they changed over at weekly intervals. They worked for six shifts, averaging 7½ hours, so the weekly total of 45 hours was not excessive. In spite of this, the absenteeism averaged 16% at Factory A and 10% at Factory B, or well above what is usually experienced in times of peace. It is therefore important to ascertain, so far as possible, the causes of the wartime excess. At Factory A it was twice as great in the morning shift as in the afternoon and night shifts, largely because of the great absenteeism experienced on Saturday mornings. No less than 46% of the married women and 30% of the single women were then absent, doubtless because they wished to go shopping, but at Factory B the Saturday morning excess was not nearly so marked. It has been suggested that the women should be asked to work on Sunday mornings instead of Saturday mornings, but numerical evidence of the effect of such a change on absenteeism is lacking. The women at the two factories in question worked an afternoon shift on Sundays, and kept nearly as good time as on other afternoons, so the experiment seems to be worth trying. The women were specially liable to lose one shift per week, and this was due mainly to different workers being absent in different weeks, and not to habitual absentees. Comparatively few workers lost from two to five shifts, but many of them lost the full six shifts owing to sickness. The causes of this sickness were not investigated in the present inquiry, but we are told that it forms

part of a larger study of absenteeism, and suggests the need for examining the personal causes of absenteeism as for an individual method of treatment, as well as attention to the general conditions of work.

EFFICACY OF LIVER PILLS

Carter's little liver pills are sold to the public as a remedy for the conglomeration of symptoms which goes under the title of liverishness. Tiredness, headache, spots before the eyes, slight nausea, and constipation have from time immemorial been blamed on the liver, and the phrase "bilious purge" has found its way into the pharmacopoeia. There is no evidence that these symptoms are due to liver disease and some of them, at least, are associated with abnormal intestinal movement. Nevertheless transient liverishness is common and can be made much of by suggestion, therefore becomes important to know on what basis claim to cure the condition rest.

Briefly, the claim is that, whereas ordinary purgatives merely cause evacuation of the bowel, Carter's little liver pills flush the poisons out of the system with two pints of bile. Each pill is said to contain 0.25 gr. of *Curaçao alo* and 0.0625 gr. of *podophylli resina*. The makers supply a sheet of instructions which tell us that the pills are the standard medical formula for waking up the liver. "The wake up those two pints of cleansing liver bile, make you whole system clean and fresh, and give you bright eye and a clear skin again." It is stated on this instruction sheet that constipation, depression, coated tongue, sallow skin, gas, and nausea are usually due to a disturbance of the normal flow of bile, and that if the liver does not pour out two pints of cleansing bile juice into the system every day, "Your food can't digest—it simply decays inside you and constipates you, and poisons you." It is probable that few pharmacologists would agree with these generous estimates of the quantity and the antiseptic power of the bile. But do Carter's little liver pills in fact promote the flow of bile? A partial answer to this question has been supplied by the recent work of Ivy, Roback, and Stein.¹ In a series of experiments on dogs they have investigated directly the effect of Carter's little liver pills on the flow of bile and on the contraction of the gall-bladder. The observations were made by tying the cystic duct, cannulating the common bile duct, and recording the pressure in the gall-bladder by means of a manometer tied into the fundus. These methods had previously been used by Ivy when he showed that an extract of the intestinal mucous membrane given intravenously would cause the gall-bladder to contract. This extract was called by him "cholecystokinin." In the present series of experiments cholecystokinin was used to show that the gall-bladder under observation was capable of contraction before and after the administration of Carter's little liver pills. Dogs weighing 15 to 20 kilos were used and the pills were injected intravenously in solution in alcohol or intraduodenally in water at body temperature. In some cases the pills were first incubated with pancreatic juice or with duodenal contents. The doses were equivalent to from two to four pills at a time. In no case did the pills produce any significant increase in the flow of bile from the liver or in the pressure inside the gall-bladder. These experiments point to a distant goal—the authoritative study of the pharmacological action of all proprietary preparations and the unbiased publication of the results.

Prof. G. Grey Turner will deliver the presidential address to the Medical Society of London on Oct. 18; his subject is "Transplantation of the Ureter."

THE PUBLIC CORPORATION

BY

D. HARCOURT KITCHIN

Barrister-at-Law

[Continued from p. 371]

Broadcasting

Wireless broadcasting in this country is administered by yet another public corporation. The B.B.C. is incorporated by charter, not by statute. This is possibly because it does not need for its work to encroach at any point on private rights; and a charter has the great advantage over a statute of obviating the lengthy and cumbrous passage of a Bill through Parliament, with its unpredictable dangers and obstacles, of being easily capable of amendment, and of allowing much greater detail. The charter and licence (under the Wireless Telegraphy Acts) both gave the Postmaster-General political, financial, and technical control. On paper, therefore, the Corporation appears to have little liberty, but constitutional practice gives it a great deal. The Postmaster-General has always, while taking responsibility for broad issues of policy, left the Corporation a free hand on minor issues, domestic policy, and day-to-day control. Its members are called governors, and they are the chairman, vice-chairman, and such other persons as the King appoints in Council from time to time. They hold office for a term stated on their appointment, not exceeding five years, and on retirement are not eligible for reappointment unless the Postmaster-General certifies that this is in the public interest. The provisional number is seven, but the Crown reserves power to increase or reduce it. The chairman's yearly salary is £3,000, and that of the other governors £1,000 each, with expenses.

A governor ceases to hold office if his appointment is terminated by the King in Council, if he holds any office or place of profit in which his interests may in the opinion of the Postmaster-General conflict with the interests of the Corporation, if he becomes of unsound mind or bankrupt or compounds with his creditors, if he resigns in writing to the Postmaster-General, or if he absents himself from the meetings of the Corporation continuously for three months without the consent of the Corporation, and the Corporation shall resolve that his office shall be vacated. The charter does not exclude Members of Parliament, but by custom a member resigns his seat on appointment. Vacancies are certified to the Crown by the Postmaster-General and filled in Council. The Corporation's chief executive officer, appointed by it, is the Director-General, and it may also appoint such other officers and staff as it may think necessary for the efficient transaction of its business, and fix their remuneration; it may remove any officer subject to its contract with him. It may meet and may make such regulations for the conduct of its business as it thinks fit, but its quorum is settled by the Postmaster-General. It may appoint committees for any purpose, and their conclusions are subject to its ratification, and it may also appoint advisers or advisory committees.

The Corporation's financial powers are specified, and its accounts are audited by chartered accountants approved by the Postmaster-General. It submits to him an annual report and accounts, and its books are subject to his inspection at all reasonable times. It may at any time apply for a supplemental charter or an Act of Parliament. The Crown keeps power to extend the operation of the charter after the time limit. Provision is made for the voluntary or compulsory winding-up of the Corporation.

The history of the B.B.C. taken as a whole does not suggest in any way that the joint-stock company form of its organization and its constitutional relations with Parliament and the public are unsuitable for its purpose. Its problems, great though they are, seem capable of solution, and its potentialities of being realized, within its present framework. The B.B.C., like the Forestry Commission and the Central Electricity Board, is especially interesting in the present connexion because it operates, as would a health services board, a nation-wide utility. Its regional organization (suspended during the war) is appointed and controlled from the centre. The autonomy possessed by

the regions has varied from time to time, but in the nature of the work must remain rather strictly limited. The suggestion has often been made that each region should be controlled by an independent corporation, but unless the "federal constitution" dividing the sovereign power between the central and the regional corporations were drawn with superhuman wisdom and foresight, the difficulties of maintaining national co-ordination would probably be too great. A better solution seems to be to have satellite regions as hitherto, but to give them as much freedom as possible and the benefit of the best possible local advice. The Corporation has elaborated in its Listener Research Department a highly effective technique of ascertaining the opinions of listeners about its various activities, and the reports of the department are carefully studied and acted on by executive officers.

National Electricity Supply

The next of the great public utility corporations in seniority is the Central Electricity Board. This body was formed by the Electricity (Supply) Act, 1926. The political tension (1926 was the year of the General Strike) was reflected in heated opposition to the Bill in Parliament as rank Socialism. Much was made of an argument which has probably by now died a natural death: that if a Socialist Government came into power the Minister of Transport could pack the Board with Socialists. In fact, appointments to such boards have never been noticeably more political than preferences to the judicial bench. The Central Electricity Board consists of a chairman and seven other members appointed by the Minister of Transport "after consultation with such representatives or bodies representative of the following interests as the Minister thinks fit—that is to say, local government, electricity, commerce, industry, transport, agriculture, and labour." The Board is broadly representative and essentially an organizing body. It is assisted in technical matters by committees of experts and by its staff. Unlike the Metropolitan Water Board and the Port of London Authority, it was not created for the express purpose of acquiring undertakings and managing them. It did this only in the last resort, when the owner would not co-operate; normally the existing owners continued to own and manage their stations. The chief property of the Board is the transmission lines.

The chairman and members are appointed for a stated term of not less than five or more than ten years. The chairman is a full-time salaried officer; the members receive honoraria. Their remuneration (an unusual provision) is in the absolute discretion of the Minister. The Board must appoint a secretary, and is given discretion to appoint other staff and pay them salaries, remuneration, pensions, and gratuities. The salaries or fees and expense allowances to be paid to members are determined by the Minister. Anyone aggrieved by a decision of the Board can invoke the arbitration of a barrister qualified for appointment to judicial office and appointed by the Minister from a panel set up by the Lord Chancellor (in Scotland an advocate on a panel set up by the Lord Provost of the Court of Session). The arbitrator may summon qualified assessors to sit with him.

The Board's success, after the failure of the Electricity Commissioners appointed under the earlier legislation to do similar work, was not due to its compulsory powers, which have hardly been used. In Gordon's opinion it succeeded because of its form: "a new administrative body, independent of existing undertakers, empowered to carry through the desired reforms." When its composition was being planned its creators naturally had in their minds the idea of a representative body on the lines of the P.L.A., but they soon found this impracticable. "The only suggestion put forward was a body representative of large consumers, ratepayers, producers, and municipalities. This proposal would have made the Board a scene of continuous conflict among competing interests with no obvious broad harmonizing influence, and no machinery to effect such harmonization outside the authority itself"—the two factors essential to the success of a representative board. The new body had therefore to be appointed from above. The Government likewise refused to give specific representation to labour and other interests—not to shut out the expression of their views but because they rightly felt that the positive action of the Board would be fatally hindered if some of its members were present for the express purpose of advancing the interests

of sections to whom they were responsible. They therefore determined on a small group of persons "of wide experience in affairs and business who, if possible, should not be directly representative of any industry, but should very impartially consider the interests of all." (*Official Report*, House of Lords, Nov. 30, 1926, vol. 5, col. 860.) The Minister was therefore given a general direction on the choice of interests he should consult.

The Government also had difficulty in deciding who should appoint the Board. The Lord Chancellor or the Treasury, it was argued, would be more impartial than a Minister and prevent undue influence over the Board's policy. On the other hand, they reflected that to associate the Board with the Treasury would tend to put it on a Civil Service basis, and to remove it entirely from the purview of the House of Commons would make impossible any ultimate democratic control over its personnel. Hence the choice of the Minister of Transport. Actually, in the first appointments, all the leading interests most closely affected, except agriculture, were represented.

Parliament has direct control over the C.E.B. and has the opportunity by Special Order of approving or rejecting its more important proposals. These are constructional rather than operational. The Board's doings have rarely aroused discussion in Parliament. As it is financially autonomous it cannot be discussed on the annual vote of the Ministry. No private member has ever moved a motion concerning it; its finances were once mentioned on the adjournment, and questions have occasionally been asked about it. The Minister of Transport answers, but successive Ministers have preferred to leave the Board to do its ordinary work undisturbed.

Ministers do not give information about the Board's own affairs except what is published in its annual reports. The only continuing control over it is given to the Electricity Commissioners. The Board's relations with distributors, owners of stations, and other interests is made subject at many points to their approval. The appeal to the arbitrating barrister was instituted because Parliament feared that the commissioners, being also appointed by the Minister, could not be trusted as a final appellate tribunal. They have actually proved to be a very good and impartial one, but the Board has succeeded so well in maintaining the good will of the undertakers by negotiation and compromise that arbitration has not been used. The commissioners have co-operated cordially with the C.E.B., and "the relations between these two bodies form a unique example of control over a public corporation combining non-political supervision with ultimate responsibility to Parliament." The positive, co-operative attitude of the Board has been the chief factor in its success despite many difficulties and handicaps. It has actively created a permanent demand for current in many directions, and carries on general propaganda of all kinds to stimulate the use of electricity. "The degree of success already achieved by it despite its limited powers is perhaps a greater tribute to the administrative potentialities of the public corporation than would be afforded were it more fully clothed with authority."

London Transport

The London Passenger Transport Board is the largest and one of the most interesting of these bodies. It was created by the London Passenger Transport Act, 1933, to provide "an adequate and properly co-ordinated system of passenger transport" for the London area. For this purpose it had transferred to it most of the electric railway, omnibus, and tram services already operating, and was directed to administer them as one undertaking. The selection of its members is unusual. At first the Government (Mr. Ramsay MacDonald's coalition) proposed that the Minister of Transport should appoint them, but for various reasons the opposition to this plan was so strong that a board of appointing trustees was formed. This consisted of the chairman for the time being of the L.C.C., a representative of the advisory committee, the chairman of the Committee of London Clearing Bankers, the president of the Law Society, the president of the Institute of Chartered Accountants, and the chairman or a member of the Board itself. The qualifications required of the chairman and members are set out in unusual detail: they "should be persons who have had wide experience, and have shown capacity, in

transport, industrial, commercial, or financial matters, or in the conduct of public affairs." Two members must be persons with not less than six years' experience in local government within the L.P.T. area. Membership of the House of Commons disqualifies. Appointment is for a stated period of not less than three or more than seven years, but after a member's term of office runs out he may be reappointed. The Minister may remove a member from office for inability or misbehaviour, but he must first consult with the appointing trustees. These words are probably quite sufficient to preclude a removal for political reasons. The agreements the Board makes with undertakings need confirmation by the Arbitration Tribunal, which may modify them. This body consists of three commissioners of whom one is president and must have legal experience, and the others must be experienced respectively in business and finance. They are appointed by the Lord Chancellor. A party aggrieved by its decisions may appeal by way of case stated to the Court of Appeal.

Labour problems are handled by a negotiating committee consisting of six representatives of the Board and six representatives of the employees, two from each of the three trade unions concerned. Questions of remuneration which this body cannot settle are referred to a wages board representing the Transport Board, the Trade Union Congress, the Co-operative Union, the Association of British Chambers of Commerce, and the National Confederation of Employers' Associations. Superannuation is dealt with fully in the Act, and a standing arbitrator is appointed by the Lord Chancellor. Existing officers and servants of absorbed undertakings were transferred and/or compensated. The Board has power to promote and oppose legislation. The Minister may hold an inquiry into any complaint made of the Board's activities. In spite of its serious financial handicap, the Board worked with great success until war broke out, when the Minister of Transport took over the administration of its undertaking along with those of the railways. Doubtless, when the emergency is over its earlier autonomy will be restored.

The unique mechanism for appointing members of the L.P.T.B. does not seem to invite imitation in later statutes. At the time it was introduced political feeling ran high, the word "nationalization" had a sinister magic of its own, and the Government of the day had no doubt that Ministers would take the opportunity to make political appointments. These appointing trustees, as Gordon points out, are entirely ignorant of the problems and needs of London traffic, and responsible to no one. They are quite unqualified for the duty of introducing from time to time suitable "new blood," fresh spirit, and ideas. The Minister, aided by the advisory committee and the advice of the interests concerned, and guided by the sense of public responsibility without which he would not have been appointed to office, is so qualified. In practice, Ministers do not abuse their power of appointment to further political ends, and to do so would involve them and their Government in a storm of criticism and condemnation that would far outweigh the advantages of the appointment. It is worth noting that the Minister may remove a member from office "for inability or misbehaviour." Whatever be the rights of the matter, the trustees (doubtless guided by consultation with the Minister) have selected a strong Board, each member of which is an expert in some aspect of London transport.

The L.P.T.B. has ample powers and autonomy for its purposes. The Minister takes no responsibility for most of its doings, and his replies to questions are mostly limited to information supplied by the Board itself. His influence over it is probably less than that of a Minister over any other public corporation, for complaints and appeals are heard by specially constituted tribunals. Most complaints about services and fares are actually made direct to the Board through its public relations office, and the appellate jurisdiction of the Railway Rates Tribunal has seldom if at all been invoked. The reconstituted Traffic Advisory Committee has been an effective link between the Board and public opinion. The Board has always been actively sympathetic to public feeling, an attitude which is common to all the public corporations and is the most important single factor in their success. It is, however, still in its youth: the developments of the period immediately after the war will test it severely.

[To be concluded]

THE ROYAL COLLEGE OF SURGEONS

PRESIDENT'S ADDRESS TO FELLOWS

A meeting of Fellows was held at the Royal College of Surgeons of England on July 21, to which members of the Association of Surgeons and their guests were invited. The chair was taken by the President, Sir ALFRED WEBB-JOHNSON, and 19 other members of the Council were present.

The President said that the Council had been encouraged by the opinions expressed at the last Annual Meeting of Fellows and Members to call this meeting; they would gladly consider the reintroduction of regular meetings of Fellows, and would like to know the views of those present. They welcomed the increased interest taken by the Fellows generally in the management of the College affairs.

College Affairs and Policy

The President referred to the recent changes in the Fellowship examinations. The primary had been made entirely a postgraduate examination, with pathology introduced as an additional subject to anatomy and applied physiology. The interval between graduation and entry for the final examination would now be two years for all candidates, provided that they had passed the primary and complied with the regulations. The Court of Examiners had been enlarged to 20, 12 members taking part in each examination. The rota system thus established, and the concentration of the examination programme, would enable surgeons with many commitments or from distant localities to serve on the Court with less interference with their other duties, and would render possible the representation of more medical schools and more specialties. Two women examiners had been appointed to the Boards of Examiners for the Conjoint Examination—one in anatomy and one in midwifery. Another new departure was the appointment of professors in the College, part of whose duties was performed elsewhere—Prof. A. Sorsby, research professor in ophthalmology, and Prof. W. E. Gye, director of the Imperial Cancer Research Fund.

The damage done by enemy action to the Royal Colleges of Physicians and of Surgeons had opened up the question of the three Royal Colleges working together either in a combined building or in adjacent buildings on some suitable site. His suggestion that Lincoln's Inn Fields had great advantages for such a Collegiate building was received with applause. The Council was prepared to consider alternative sites, but the present building of the College of Surgeons and the adjoining sites owned by it might provide an area more than sufficient for the requirements of the three Colleges and for future developments. In the opinion of the Council the suitability of the Lincoln's Inn Fields site should be seriously considered and should not be lightly rejected, as the value of the buildings still standing was estimated at £200,000.

The position in the College of the special branches of surgery was an important matter, and the Council was sensible of the necessity for catering for their needs in such affairs as representation on the Council and the granting of suitable higher diplomas. The recent change in the format of the Council election papers had been designed to emphasize the importance of the Council's being largely representative of the medical schools and of general and specialist surgery throughout the country. The training of surgeons was another matter now receiving active consideration, and the President advocated an interchange of views between the Royal Colleges of England and Edinburgh and Ireland in regard particularly to examination in the basic sciences, to the place of special subjects in the final examination, and to the length of the interval between qualification and taking a higher diploma. The Council had declined a suggestion that Fellowship examinations should be discontinued during the war.

Criteria for consultants had been provisionally agreed by the Standing Joint Committee of the Royal Colleges of Physicians, Surgeons, and Obstetricians and Gynaecologists for the guidance of the newly formed Central Medical Academic Council, composed of representatives of the Royal Colleges and of the medical faculties of the universities. These criteria, however, could not yet be regarded as settled.

Representatives of the Colleges had given evidence before the Interdepartmental Committee on Medical Schools (the Goodenough Committee). The President reported the very definite view of the Council that there must be a portal to the medical profession under the sole control of a purely professional body, and the College had therefore disagreed with the suggestion that a university degree should be a *sine qua non* for medical qualification. (Applause.)

The Beveridge Plan

A Representative Committee of the profession was engaged in discussions with the Minister of Health. The Royal Colleges were represented by their Presidents, and he himself had insisted that he must be regarded as a representative of consultant surgery. For this purpose the Royal Colleges had held a conference of representatives from all centres in order to obtain the views of consultants throughout the country. The Representative Committee maintained that some freedom of choice must be left both to doctor and to patient, and declined to countenance the conversion of a free profession into a public service. An individual must be free to enter the medical profession and to practise his profession when registered. The medical profession must have a large say in the organization and management of a National Health Service. The administrative structure must therefore be such as to allow of a generous representation of the medical profession. The health service must be really comprehensive in character; the local authorities as at present constituted did not provide satisfactory areas for dealing with the needs of the population. Some scheme of registration was essential. It was the declared intention of the Government that opportunities for private practice should be maintained, and the most sensible and reasonable way of providing for this seemed to be to apply the national contributory scheme only to those who needed such provision. It was generally agreed that in planning for "positive health" and the prevention of disease the non-medical proposals of the Beveridge report were of far greater importance than any revolutionary changes in medical practice. He referred particularly to the improvement of housing, the avoidance of mass unemployment, the provision of children's allowances, disability pay, and old age pensions.

Resolutions passed by the Meeting

1. Moved by Surg. Rear-Adml. ROBERT MILNE and seconded by Col. F. P. MACKIE: That this meeting of Fellows welcomes the opportunity which the occasion has provided for consultation and for informing them of the proceedings of the Council, and hopes that the Council will arrange for meetings of Fellows on future occasions.

2. Moved by Brig. A. HEDLEY WHYTE, and seconded by Mr. G. T. MULLALLY: That this meeting of Fellows welcomes the various changes which have been made by the Council and approves of the line of policy outlined in the President's report.

3. Moved by Mr. W. MCADAM ECCLES and seconded by Mr. R. M. HANDFIELD-JONES: That this meeting of Fellows hereby expresses a hearty vote of thanks to the Council for arranging this meeting, and in particular to the President for the way in which he has conducted it.

DOMICILIARY NURSING SERVICES

Seven secretaries of District Nursing Associations—one in London and the others in the Midlands and the North—have produced an account of the actual conditions in district nursing, midwifery, and health visiting,* well worthy of attention in the light of the many proposals for reconstruction of social services. It is a record which comes down to "shillings and pence," setting out the precise facts and figures for recruitment, training, living conditions, hours on and off duty, salaries, future prospects, and pensions, and a review of the Canadian Home Nursing Service is given for comparison. Proposals are made for the better regulation of off-duty times for district nurses, also for a unified pension scheme or for interchangeability between existing schemes for all these workers. The review leads up to a recommendation that a national body should be set up under the auspices of the Queen's Institute, charged with the duty of formulating a national provident or contributory scheme for district nursing to cover the whole country and also to secure greater uniformity in the nature and basis of grants received from public funds. At present the grants are left to the discretion of each local authority.

Nova et Vetera

SALERNO: ITS MEDICAL SCHOOL AND ITS MEDICAL LEGENDS

Salerno, the first important town on the European continent to be occupied by the Allies, has a special place in medical affection. It is the site of the earliest "modern" medical school. Its very name conjures up romance. A note on the school and on some of its early legends may be welcome.

During the "Dark Ages"—that is, from about A.D. 400 to about 1200—the great tradition of Hippocrates and Galen faded. All theoretical medical knowledge lapsed. Even the bare elements of anatomy were forgotten. Prognosis became a childish rule of thumb; therapeutics a ridiculous and disgusting drug list; medicine a collection of formulae punctuated by more or less sacred incantations. Yet there was one area where a slightly higher standard prevailed. In South Italy dialects of Greek were spoken, and there a faint travesty of the ancient medical learning still lingered. This was notably the case at Salerno. Of physicians in its neighbourhood we get a few glimpses in the eighth and ninth centuries. By the middle of the tenth century the fame of the place as a medical centre had reached far afield.

Many romantic legends have gathered round the name. Fancy has promoted the "ladies of Salerno" into the first corporation of women doctors. The first modern anatomical text is Salernitan, and it appropriately substitutes the structure of the pig for that of man. The most famous of medical poems, the "Salerne School," has been turned into every language. Some of the MSS. are addressed to "England's king," held to be William the Conqueror's eldest son, Robert of Normandy (1054-1134), who was certainly in Salerno in 1098. Two of the opening lines of the poem are known to all:

"Use three physicians still. First Doctor Quiet,
Next Doctor Merryman, and Doctor Diet."

Perhaps the oddest of the Salerno legends ascribes the foundation of the school to four practitioners—a Greek, a Latin, an Arab, and a Jew. None of the current romantic stories about the early days of Salerno is even approximately true, but the last, suggesting a mixture of four cultures in this region, does faintly reflect an actual situation.

A Battleground of Interests

After the fall of the Gothic power in the sixth century South Italy became for centuries a battleground of conflicting interests. It was a mosaic of small States, usually under the nominal rule of Byzantium and influenced by a variety of cultures. Invaders from the north seldom reached the south, and Byzantium, securely ensconced on the Adriatic seaboard, disputed the mastery with native chiefs and, from the eighth century onward, with Saracens also. The prevailing language was largely Greek, of which the colloquial speech bears traces to this day. The imperfect grasp of the Byzantines, however, gave opportunity for entry of other tongues. Latin dialects were spoken in many places. In others Greek dialects were placed by forms of Arabic patois. Moreover, material and literary remains tell of a vigorous development of a Hebrew culture in this region. We devote a few sentences to the little-known Saracen and Jewish elements.

In the seventh century the dominion of the Crescent had extended along the southern shores of the Mediterranean, from the Red Sea to the Atlantic. In 711 Tarik crossed into Spain with a Berber army and gave his name, the Mount of Tarik—Gebel Tarik—to the natural fortress the title of which has been corrupted into Gibraltar. This movement that carried Islam across the narrow Strait of Gibraltar threw it across the wider Sicilian Channel in the eighth century and on to the mainland in the ninth. In 827 the Emir of Kairouan in Tunisia began a systematic invasion. Palermo fell in 831 and was a strong base for raids on the Italian coasts. Things moved more slowly in those days than in these, but in 846 the arms of the Crescent were carried to Rome itself. At Salerno and elsewhere Saracen colonies were established.

For our knowledge of the Jewish element in South Italy at this period we have a Hebrew chronicle from 850 to 1060.

telling of many Jewish settlements in the Salerno area, a Hebrew medical work of about 950. But above all we have the extensive Latin writings bearing the name of Constantine the African. He was an Arabic speaker who made a long stay in Salerno, was converted to Christianity, and became a monk at the ancient Benedictine house of Monte Cassino. Constantine died in 1087. He spent much of the last ten years of his life turning into Latin, with help of a local scribe, medical works of certain Jewish physicians of Kairouan. At the same time an Archbishop of Salerno was engaged in translating medical works of Greek into Latin. Constantine himself is said to have acted as the oriental secretary of the Norman invader of Salerno.

End of the Great Medical Period

These literary events were contemporary with the Norman conquest of Sicily and South Italy, which was itself contemporary with the Norman conquest of England. There was some intercourse between Salerno and England, and one of the few surviving Anglo-Saxon medical texts, written soon after the Norman Conquest, is a translation of a Salernitan document. This was the great period of the medical school of Salerno. During the twelfth century Bologna, and later Padua, became the chief medical centre. In 1224 a university was formally instituted as a rival to papal Bologna by Frederick II, the great enemy of the Papacy, at Naples. This was fatal to the neighbouring medical school at Salerno and its importance began immediately to wane. Literary activity continued to some extent and the school prolonged an ever more feeble existence to the very end of the eighteenth century. Gradually, however, it became a place of bogus degrees and not of authentic ancient memories. Napoleon closed it finally in 1806. Since then its literature and its legendary associations have provided much fruitful material for medical historians, and not a little for writers of romance—medical and other.

C.S

Correspondence

Early Recognition of Cancer

SIR,—Everybody will agree with your correspondent I. Joseph Walter (Sept. 4, p. 313) concerning the necessity of making the public cancer-conscious. I would, however, like to point out that for four years before the war the British Empire Cancer Campaign had been carrying out work on this subject through its Central Propaganda Committee by means of educational publications and lectures. In 1936 arrangements were made by the Campaign for lectures to be given to the public, and these were only discontinued because of the war. During those four years 35 counties were covered and in 1,256 lectures were given to audiences totalling 57,851—an average attendance of 46. The lectures were given by medical men after they had been "briefed" by the committee and given skeleton lectures on which to base their own talks. The audiences consisted largely of members of the Women's Institutes, Townswomen's Guilds, National Council for Women, British Legion, Rotary Clubs, T.O.C.H., etc. At the lectures nearly 750,000 educational leaflets were distributed.

When the suggestion was first made that lay lectures should be given there was considerable opposition on the ground that cancer phobia would be caused among the public. The very numerous spontaneous letters received from individuals in the audiences who attended these lectures convinced the committee that this was not true, and indeed it is quite obvious that knowledge is the only way of getting rid of cancer phobia which afflicts so many human beings. Although it is hoped that the Campaign will be able to carry on this work after the war, nevertheless I feel that this very important method of getting early diagnosis will have to be taken on by the organizations which will be set up under the new Cancer Act—I am, etc.,

MALCOLM DONALDSON,
Chairman, Central Propaganda Committee,
British Empire Cancer Campaign.

Perforated Gastric Ulcer in Youth

SIR.—In your issue of Aug. 21 (p. 256) Dr. M. A. Conyngham mentioned a case of perforated gastric ulcer in a boy of 17. His calamity has occurred at earlier ages.

In 1910 the late Sir Joseph Leech of Newcastle-upon-Tyne operated on a boy of 13 who presented a perforated ulcer on the anterior surface of the stomach near the pylorus. He suffered from a second perforation at the age of 16 and a third at 18, when I had to deal with an ulcer at the cardiac end just in front of the hilus of the spleen. During convalescence he had a severe attack which led me to reopen the abdomen in the confident expectation of finding

fourth perforation. But no, a perisplenic abscess had burst and suddenly flooded the peritoneal cavity. According to the practice of those days, the belly was thoroughly irrigated and drained, and, in the hope of cutting short these catastrophes, I made a gastro-terostomy, which had to be anterior. Three weeks later, when he thought he was about ready for discharge, he developed acute intestinal obstruction, which further laparotomy revealed to be due to bands among coils of small bowel. By this time the Kaiser's war was in full swing, and at a critical stage my patient was accepted for service and soon found himself in France, where he enjoyed excellent health. On the cessation of hostilities a return to civil life and work in the coal mines was followed by an attack of subacute obstruction, which yielded to non-operative management. But his work did not prove suitable, and a return of indigestion was followed by an attack of severe haematemesis. After much medical care he left the North and adopted an open-air occupation, which seemed most suitable, for he was rewarded by a return to a long period of quite good health.

Just before this war—some 28 years since his first perforation—this man again came under my care, in poor condition, with great pain and much abdominal tenderness. Laparotomy confirmed the presence of a secondary peptic ulcer at the site of the anastomosis, with some obstruction among the small coils from strong bands. Recovery was quick and for some two years complete, but since the Coventry "blitz" I have not been able to trace my old friend.

If I were reporting this case, apart from the interest of the early age of perforation, it would have been under some such heading as "The Persistence of the Peptic Ulcer Tendency."—I am, etc.,

British Postgraduate Medical School.

G. GREY TURNER.

X Rays and the Colon

SIR.—I was present at the meeting to which Sir Arthur Hurst refers in his letter (Sept. 4, p. 310), and was sorry that he had not time to qualify what appeared to be a sweeping condemnation of barium enemias as an aid to the diagnosis of spastic colon.

His letter suggests that he has been unfortunate in some of his radiologists, as I have not come across the specialist radiologist who has given "radiological reports ascribing symptoms to various x-ray findings." I have always understood that one should report the x-ray appearances with their significance to the doctor and not the patient, bearing in mind that ours is only an aid in the complete investigation of the case.

Most of us are chary of diagnosing a gastro-intestinal case on a skiagram without screening. Although we may sometimes see our mistakes when we know the surgical or post-mortem findings, I doubt whether as a class we are as exceptionally ignorant as the letter appears to suggest, although a few radiologists at large hospitals may be appointed without the desiderata of a large radiological and general experience.—I am, etc.,

Richmond.

DENYS B. I. HALLETT.

Stilboestrol for Prostatic Enlargement

SIR.—There seems to be neither rhyme nor reason in this treatment. A measure of success has been claimed without serious attempt to explain the *modus operandi*.

Actually the side-effects provide the clue, gynaecomastia being an invariable accompaniment of large dosage of stilboestrol in the male. In effect stilboestrol in the male stimulates the rudimentary female structures into activity; the larger the dose the greater the activity. In the case of simple enlargement—i.e. adenoma—or of cancer of the prostate there is nothing to support the view that stilboestrol directly affects the new growth. I suggest that if the case be treated with large doses of stilboestrol at any stage where the original prostatic

tissue has not been entirely replaced, the prostatic tissue remaining will be so strongly stimulated to activity and growth that it will take the upper hand and will inhibit further encroachment by the neoplasm.

It would follow from this that the entire prostate might be considered to be a rudimentary female structure—not so fantastic a view, perhaps, when it is considered that the prostate has yet to reveal its function.—I am, etc.,

J. A. L. MAGEE, M.B.

H 11 for Cancer

SIR.—Regarding reports on the value of H 11 and other drugs used in the treatment of cancer, it would be of value to have fuller reports on the cases which are cited in your correspondence column and for which vague cures and inhibitory actions are claimed.

Dr. J. H. Hannan writes in your correspondence column (Sept. 4, p. 314) that he had success with H 11 in a case of carcinoma of the vulva where radium and x-ray treatment failed. There is no mention here of a biopsy having been taken. Does the author of the letter really know whether there was a recurrence? Is he acquainted with the numerous cases where radiotherapy has appeared to fail and later the "recurrence" is found to be of a simple inflammatory nature?

If we are to assess these drugs, it is essential that accurate scientific case records should be made, and a diagnosis of malignant disease without histological confirmation cannot generally be accepted. This would seem to be especially important where a recurrence of malignant disease is suspected.—I am, etc.,

GEORGE W. BLOMFIELD,
Medical Director, Sheffield Radium Centre.

SIR.—With reference to H 11, it may be of interest to record the results of treatment by my colleagues and myself in fairly advanced cases of (1) rectal cancer; (2) sigmoid cancer; (3) secondaries following ovarian cancer; (4) secondaries following breast cancer; (5) ulcerating breast cancer. Treatment in each case failed and the patient died from cancer. In the first 4 cases treatment was prolonged and intensive. In Case 5 treatment with H 11 was discontinued after 2 months as no improvement was apparent.

It is also claimed that H 11 ointment will remove warts, and although it has been used in one case consistently for 3 months, no improvement was observed.

It will therefore be seen from the above that our results were completely negative.—I am, etc.,

Birmingham.

IVOR RADNOR, M.B.

The Mastoid and D. and V.

SIR.—May I take this opportunity of replying to the criticisms which my paper on this subject has provoked.

Dr. McGuckin (Aug. 21, p. 245) asks for proof of the presence of mastoiditis; if his interest in the subject is deep enough for him to be present at a few operations his doubt will be satisfied. He expresses distress that children should be condemned to a double mastoidectomy because a gland in the posterior triangle can be rolled under the finger; I share his distress. Should he refer to my paper he will find that no such suggestion is made. It is definitely pointed out that glands in the posterior triangle are an important physical sign among others as an aid to diagnosis. Dr. McGuckin also asks for proof of my statement that all the patients I have operated on would have died without surgical aid. I would point out that progressive mastoiditis is a fatal disease unless treated surgically.

Dr. Worrall's letter (Aug. 28, p. 280) is important, and his suggestions with regard to parasympathetic over-activity and shock should prove of value to physicians. It may well be that suitable treatment with ephedrine, atropine, and HCl will prevent a catarrhal mastoiditis becoming purulent, thereby rendering surgical treatment unnecessary.

Dr. Bruce Williamson's experiment with charcoal was unknown to me; I thank him for bringing it to my notice. With regard to proof of mastoiditis before the onset of diarrhoea and vomiting, I would point out that it is not uncommon to see patients in hospital who have recovered from some airborne infection who develop fever, head-rolling, crying out, and

putting a hand to the head; in addition such cases may present pink tympanic membranes and enlarged glands in the posterior triangles before the onset of diarrhoea and vomiting.

Dr. Emily Simon's letter is of special interest. I have several times diagnosed petrositis before operation, and in two such cases have seen the sudden onset of a double sixth-nerve palsy which has cleared up after operation (double Gradenigo's syndrome). I think it unlikely that petrositis can occur except from an antecedent mastoiditis.—I am, etc.,

Birkenhead.

P. W. LEATHART.

Health and Tonsillectomy

SIR.—In mass investigations into the results of tonsil and adenoid operations upon ear trouble (Sept. 11, p. 334) it is necessary to realize that a previous history of otitis media probably means that the affected ear is a "weak spot." It is not reasonable to expect tonsillectomy and removal of adenoids to cure temporal bone disease.

With regard to the common infectious diseases of childhood, tonsillectomy does appear to prevent faucial diphtheria. Neither the guillotine nor the dissection method gives as a rule 100% of perfect results. It is, apparently, some of the "tonsillotomies" which are referred to in the statement that the tonsillectomized group had a 1% record of tonsillitis compared with 5% for the other group.

Careful mass investigation results would be useful as to the effects of tonsillectomy upon tuberculous adenitis (there seem to be fewer scarred necks nowadays). Reports dealing with the incidence of colds might deal with the question whether adenoid "recurrence" had taken place and whether the nose and maxillary antra were healthy or not.—I am, etc.,

Manchester.

W. BRYCE MCKELVIE.

Artificial Insemination

SIR.—I am afraid that I cannot agree with Dr. Mary Barton in her easy assumption that artificial insemination is—to use her own phraseology—medically, ethically, or socially justifiable.

Medically it may work. If eugenists are consulted, it is possible that a woman may be able to produce a magnificent animal by artificial insemination, whether from her husband or some other selected stud male. But—and here the social aspect is involved—is a fine body of a man or woman necessarily socially desirable? Dr. Barton seems to forget that men are not cattle, and that the sex life of animals is far simpler than that of man. Man has a mind, which is formed far less by the magnificence or otherwise of his body—important as this may be as a contributory factor—than, so to speak, by a subtle form of gestation as between the minds of his parents.

Even if no ethical grounds can be found against artificial breeding, we are up against very practical psychological objections. It may well be that certain primitive types of women might not suffer any trauma, nor the offspring either. But we do not want the primitive to breed so much as the intelligent, cultured, and sensitive, who are the real assets to the community. And it is here, if nowhere else, that the methods advocated are bound to come unstuck. Any woman I have spoken to is revolted at the idea of artificial methods being used: they feel it violates something sacrosanct as between them and their husbands. Occasionally the maternal impulse is so strong that they will put up with it—provided the husband is the father of the child. But I have yet to meet one to whom the idea of insemination by a stranger is not anathema. In some measure this applies also to the husband's attitude.

But what of the child? I know very well, from my experience in psychotherapy, of the deep scars left on the mind of a child which is not produced under the best conditions—which are those of mutual love, leading to sexual intercourse for the purpose of producing that child. Where so intimate and sensitive a thing as the sex relation between cultured people has been tampered with, I think it is certain that the child must suffer. And when a psychologically damaged child grows up, society suffers too.

Man may be an animal. But he is animal *plus*, and I think that before plunging into human stud-farming this must be taken into account. Man has the animal instincts and desires in him, and they need to be dealt with adequately. But happi-

ness is not necessarily the result of fulfilling these instincts *tort et à travers*. As has been pointed out, humanity need be sure that its instincts are made to subserve human teleological ends, and there are occasions where these involve sacrifice even of so primal a need as maternity.—I am, etc.,

London, W.1.

L. J. BENDT, M.I.

SIR.—The medical profession seems for long light-hearted to have been making it possible or at least easier for diabetic young cases of pernicious anaemia, mental defectives, etc., reproduce themselves. Surely we ought to stop short on sentimental journey and consider whether enabling those who are sterile without artificial aid to reproduce is really likely to be an effective long-term contribution towards increasing the birth rate. Is not this one of the essential points which Dr. Mary Barton so much wishes us to consider.—I am, etc.,

London.

C. RICKWORD LAW.

Induced Pneumoperitonium: A Fatal Case

SIR.—In view of the interest aroused by the discussion of peritoneoscopy recently published in the *Proceedings of the Royal Society of Medicine* (July, 1943) and reported in the *Times* (Aug. 25), in which the safety of the procedure is stressed and no death attributable to it recorded in a large series of cases, it may be worth recalling a case in which injection of air into the peritoneum proved fatal owing to a rare anomaly.

In 1924 or 1925 I witnessed what was, I believe, the first induction of pneumoperitoneum for the purpose of radiography carried out at a certain teaching hospital. The patient, a young woman, was suspected of having tuberculous mesenteric glands. Almost as soon as the induction had begun she became dyspnoeic and complained of pain in the chest. The flow of air was stopped, and resumed after a few minutes. She then collapsed, the needle was withdrawn, she was returned to bed and died soon after. The post-mortem showed bilateral pneumothorax with collapse of both lungs. A number of small holes were discovered in the diaphragm connecting the peritoneal with both pleural cavities. I have no access at the moment to reference books, but presumably persistence of pleuroperitoneal communication is very rare.—I am, etc.,

Lincoln.

C. NEWLYN SMITH.

Specialist Courses for Service M.O.s

SIR.—May I endorse most emphatically the opinion of L. W. Aldridge so ably expressed in his letter (July 17, p. 38). The opportunity to resume postgraduate study with a view to higher qualifications ought to be extended to every ex-Service medical officer who desires it after the war, and should not depend on the private financial resources of the individual.

The value of the work done by young specialists in B2 jobs in the E.M.S. cannot be questioned; but it is equally beyond dispute that the sacrifices they have made and the risks they have accepted do not compare with those borne by their colleagues in the three Services. Yet after the war is over, unless the Government and the teaching authorities of the profession have ready a scheme such as Dr. Aldridge suggests, the ex-Service doctors cannot hope for equality of opportunity with their civilian contemporaries.

I have twice raised the point with the British Medical Association during the war. A reply by the Deputy Secretary stated: "No ex-Service doctor will be handicapped either in competing for appointments or in postgraduate study by reason of his service with the Forces." So far from reassuring me, it must confess this caused me considerable misgiving. For one thing it ignores completely the fact that the handicap already exists and must be overcome, not overlooked. For another, while undoubtedly offered in good faith, its comforting optimism is disagreeably reminiscent of some of the promises held out during the last war. It is natural that some medical officers should be far more concerned with their chances of becoming surgeons or physicians after the war than with the terms or conditions of post-war general practice. Such doctors neither ask nor expect preferential treatment, but they do look to the teaching institutions and the Government for an opportunity when their present job is done to equip themselves to follow their particular vocation.—I am, etc.,

D. STAFFORD-CLARK, M.B., B.S.

Refresher Courses for Service M.O.s

SIR,—Under conditions of active service the work of the gimental M.O. is limited to a small variety of cases and large amount of his time is spent on strictly non-clinical objects; all the really ill men are sent to hospital, and more ten than not it is impossible for him to check his diagnosis.

This kind of work it is very difficult to preserve one's knowledge and the truly medical atmosphere of the teaching hospital and of civilian practice.

I have discussed this problem with a number of young medical officers out here. We all feel that after the war refresher courses at all teaching schools and hospitals will be urgently required for the young qualified men who have returned from the Services to take their place in civilian life. This should be the responsibility of the State, who sent them to war and who will need them efficiently equipped for the requirements of civilian practice.—I am, etc.,

B.N.A.F.

C. GILES.
Capt. R.A.M.C.

Public Opinion on Health Services

SIR,—I welcome Dr. Shackleton Bailey's rejoinder (Sept. 4, p. 311) to my letter if it leads to clarification of the issues involved and enables me to correct the unfortunate impression it seems to have gathered that I was either sneering or contemptuous, for I was innocent of any such thought or feeling.

I think Dr. Bailey's objections arise mainly from a difference of outlook or experience rather than any dispute about facts. If his pessimism is justified his conclusions may perhaps be also. I know enough about medical practice to realize that *The Citadel* is not all exaggeration, but I still have greater confidence in both my professional brethren and my fellow citizens than he appears to have. I do not believe that most doctors are seriously tempted to bow to the popular clamour of the patient, as he implies, and I am perfectly sure that most patients do not value their doctor in the proportion to which he gives way to them, but in proportion to the way in which he seems to understand them and their difficulties as well as their diseases, and also on the extent to which he gives them disinterested advice.

Dr. Bailey's doubts are also shown in his first letter, where he specifically speaks of a "less stable body of opinion" as marking the democracy of the future. In so far as this is a correct judgment it can only mean an opinion less instructed in the points at issue, in fact exactly what I call "ill-instructed popular clamour." I believe it is the duty of the profession to see that so far as possible the electorate is well instructed about matters of health, and I am quite sure that so far the electorate, and possibly Parliament itself, are woefully ignorant about the implications of the proposed changes in the medical profession, some of which are specifically mentioned in the Beveridge report. So far people have been feasting on the sugar of the pill—to which they are welcome—but some of us are genuinely concerned whether the bitter part of the pill is finally going to make the patient better or worse. To take one small example. Paragraph 426 states that "it is a logical corollary to the receipt of high benefits in disability that the individual should recognize the duty to be well and to co-operate in all steps which may lead to diagnosis of disease in early stages when it can be prevented." This sounds admirable, but in fact it means that under the Beveridge scheme, if the doctor advises a barium meal, a biopsy, or the extraction of teeth, etc., the patient will be in duty bound to submit or forfeit his benefits. Are we doctors really so confident in our omniscience that we think it wise to put the patient in such a dilemma, and are high benefits wisely purchased at the price of personal liberty? Is it really better to force a person to do right than to allow the possibility of making mistakes, which is the inevitable price of moral choice and the development of personality? Many such problems arise both for patients and for doctors, and few of them have been propounded to the electorate, in whom, for years to come, these fundamental issues will bring forth good or evil fruit. Until these have been faced how else can one describe popular opinion as anything else but ill instructed?

Dr. Bailey's letters are nearly all politics, so may I make one observation about the constitutional issues he raises? While

no one would challenge the authority of Parliament, according to the Constitution it should have been dissolved nearly four years ago. Few believe that it now represents the true feeling of the country, except in our desire to win the war. The Government has itself recognized these facts by promising that it will not introduce any controversial legislation. Few topics could, however, be more controversial than to alter the status of a whole profession. If this were essential for the continued existence of the nation or even a fundamental condition for its social progress we could hardly demur. It is, however, as Beveridge himself recognizes, only incidental to his scheme, which specifically avoids laying down any conditions about the way medical attention should be obtained. The demand for it is political, pure and simple. As such we have every right to resist it, and should, in fact, be perfectly within our legal rights in refusing point blank to accept it. It is no function of democracy to expropriate any body of citizens and forcibly alter their conditions of employment, apart from the extreme necessities of war. If we doctors need more clear thinking and plain speaking on these subjects, how much more the millions who, in spite of Dr. Bailey's doubts, do look to doctors to give them sound advice, even though, like a night call, it might be to our own inconvenience.—I am, etc.,

Winsford.

W. N. LEAK.

Unity in the Profession?

SIR,—The statement in Dr. George F. Buchan's letter (Aug. 28, p. 278) that "the Society of Medical Officers of Health does, in fact, support the policy of a whole-time salaried service, but they do not suggest its immediate adoption" demonstrated the difference in outlook of doctors who are in private practice and the public health officials. We hear a lot about "unity of the profession" from the leaders of the B.M.A., but how can this be possible with such divergence in ideals of practice? Dr. J. M. O. Rees of Guildford (*Supplement*, Aug 21, p. 25) has pointed out very clearly the differences in the three types of service. By far the major portion of us in private practice do not desire any form of State-controlled salaried service. We are determined to keep our freedom.

Dr. Buchan in his clear exposition, which leaves no doubt as to the views of his society, says there is "no hurry" and gives very good reasons. The Government, however, in the meantime could make all necessary arrangements for central and local control, and in that transition period "all reasonable methods of medical practice should be tried out before any final conclusion was reached." This plan detailed by Dr. Buchan, this transitional period of experimentation, this play with doctors, exposes the cold official mind of the public health officer. It is rather a cruel try-out and would be a torture to the great majority of practitioners. Remember Dr. Buchan was chosen to serve on the Representative Committee. Do you desire men of his outlook—control and regimentation—to be elected to the Negotiations Committee?—I am, etc.,

Bradford.

DONALD WATSON.

Hospital Posts under Local Authorities

SIR,—I must admire the honesty and courage of "Former Councillor" (July 10, p. 54). It raises an issue which the profession should seriously consider when discussing the future of medical practice in this country after the war. His remarks from the point of view of the councillor prompts me to put on record a few of my own experiences as a candidate for hospital posts under local authorities.

About eight years ago a certain city council advertised for R.S.O. to their city hospital, stressing the necessity that candidates should possess the F.R.C.S. diploma together with experience of operative surgery. A preliminary short list of six was drawn up. Three candidates in this list possessed the F.R.C.S.Eng. and all were men with operative experience. The other three were "local" men, not one of whom possessed the F.R.C.S., but one of them held the D.P.H. and had been for some time a schools medical officer. This latter candidate, however, had one qualification which proved to be a trump card—to wit, he had "influential" friends on the selection committee. Before the final selection the three Fellowship men were, with one stroke of the pen, excluded from the list, and at the interview the gentleman with the D.P.H. was duly appointed to the post of R.S.O. to the hospital.

By a curious coincidence the same post—at the same hospital—again became vacant and was duly advertised. Once again the council was most insistent that the candidates must possess the F.R.C.S. diploma and "must have had extensive postgraduate operative experience." This time four candidates were short-listed—two "local" men and two others. Neither of the two "local boys" had been qualified more than 3 years, neither possessed the F.R.C.S., and neither could be described as having had extensive postgraduate surgical experience. The other two candidates, were both over 30 years, both held the F.R.C.S. diploma, and both had had at least 10 years of hospital surgical experience. At the interview one of the "local boys" was appointed. To quote a familiar expression, "The job had been cooked." It later transpired that the appointed man was well known to and "liked" by the medical superintendent—not to mention members of the committee. The disappointed candidates collected their "travelling expenses" and left the scene, dazed and embittered and wondering what sort of a profession is this that can tolerate such gross injustice. After this experience I became quite convinced that the possession of a higher qualification could prove to be a serious handicap to a candidate when applying for a post in a hospital at which the medical superintendent himself did not possess any higher degrees.

This system whereby lay committees appoint medical men to hospital and other posts is both ridiculous and demoralizing. After many years of professional training a doctor finds himself thrown on to the tender mercies of lay councillors who frequently cannot tell one diploma from another, and are often completely incapable of distinguishing an experienced surgeon from a newly qualified man. In my experience, lay committees are far too frequently infected by "local politics" and "graft" to be relied upon to give medical men a square deal at interviews. Medical appointments should be made by a body of completely impartial medical men who would see to it that the best man gets the job. If we are to have a form of State Medical Service we must see to it that the control is "medical."—I am, etc.,

EDGAR W. THOMAS.

Fitness for Factory Work

SIR,—I have the impression that medical boards and practitioners, consciously or unconsciously, are passing girls and women fit for work in factories or in the N.A.A.F.I. who have not made the grade for the women's Services—e.g., the A.T.S., etc. Some of those girls shortly after their call-up to the factories are being sent back home in a worsened state of health. In not a few cases they may, as a result of thoughtless direction to such work, suffer the consequences for a long time, if not for life. If a girl is unfit for the women's Services she is still less likely to be fit for the N.A.A.F.I. or work in a factory, which is infinitely heavier and more exacting besides having longer hours. I wonder if it is the question of pension which is the deciding factor whether medical boards direct that a girl is fit or not for the Services?

How is it that girls who are unfit for the Services are referred to the Labour Exchange as fit for posting to factory work, etc., and to almost any part of the kingdom, with little or no reference to their previous medical history or home environment? At the last minute I stopped a girl who had had recently active tuberculous glands of the neck being sent from a comparatively healthy country atmosphere to a factory in an industrial town. I think it is the duty of the doctor to safeguard the interests of his patients. Is this not a very important field for the family doctor to make sure that at least his patients are fairly treated and not directed to work which may affect their futures?—I am, etc.,

Dingwall.

KENNETH I. E. MACLEOD.

Masseurs in the R.A.F. Medical Service

SIR,—I should like to correct a statement made by Dr. G. L. Kerr Pringle in his letter (Sept. 11, p. 341) that the Royal Air Force Medical Branch does not employ male personnel in massage. I may state that 50% of the medical orderlies employed in massage in the R.A.F. are male orderlies. All of these male orderlies are fully qualified masseurs, being either civilian or Service trained, and either being in possession of the necessary civilian certificates or having passed the necessary Service tests and examinations to qualify as masseurs.—I am, etc.,

D. McLAREN.

Air Ministry, W.C.2.

Obituary

SIR WILLIAM WHEELER, M.D., F.R.C.S.I.
Consulting Surgeon to the Royal Navy in Scotland

Sir William Ireland de Courcy Wheeler, whose death took place suddenly in Aberdeen on Sept. 11, will be mourned by many on both sides of the Irish Sea and across the Atlantic. He was not only a brilliant operating surgeon, a clinician of much wisdom, and an authoritative writer on surgery, but a man with a great capacity for friendship. The relation of the surgeon to his patients is, in the nature of things, occasional, and less likely to be productive of friendships than the relation of the physician or the family doctor. But with Wheeler the making of friends and the inspiring of affection amounted to a sort of genius. He was a man to whom people gravitated, not only for surgical help but for general advice and guidance. When, 11 years ago, he left Ireland for England many expressions of regret and farewell were tendered by bodies over which he had presided and social circles in which he had moved, but none touched him as deeply as a testimonial from numbers of his old patients in County Kildare, where he had had his home, as his father had before him.

(Press Portrait Bureau)

It was in Dublin that he made his reputation as a surgeon, but long before he left Ireland his reputation was as firmly established in Great Britain. He had been for many years a leading figure in the interchanges of British and Irish medicine, with which politics has never been suffered to interfere. He was known as a writer of one or two textbooks and of many monographs on surgical subjects. His outstanding work in the war of 1914-18, when he served in France with the rank of lieutenant-colonel and was mentioned twice in dispatches, and knighted at the end of the war, had brought him into close association with his British colleagues. His work in orthopaedics, as head of the military surgical centre at Blackrock, near Dublin, had led to a close friendship with the late Sir Robert Jones and other orthopaedic surgeons on this side, and Wheeler served on the Advisory Council on Artificial Limbs to the Ministry of Pensions. In the British Medical Association, again before he settled in England, he had been a member of the Council and of the Irish Committee from 1926 to 1933, and was largely instrumental in bringing about the highly successful meeting in Dublin in 1933. Nothing gave him greater pleasure than to support the presidency of Dr. Moorhead, his old friend of forty years' standing.

The occasion of his leaving Ireland for London when he was already over fifty years of age was the opportunity offered to him by Lord Iveagh, a member of the Guinness family in Dublin, who had given nearly £200,000 towards making a new hospital at Southend-on-Sea one of the finest for its size (ultimately 400 beds) in the country. The surgical block comprised the newest type of operating theatres and accessories, and Lord Iveagh persuaded Sir William to accept a position on the visiting staff. With this appointment at Southend he combined an appointment at All Saints' Hospital for Genito-urinary Diseases, London, for although he was a general surgeon, or an "operating physician," he cultivated urology as what he called a "side-line." One of his beliefs was that the best urologist—and no doubt the same held good in his opinion for other branches of medicine—was the general surgeon who, as a kind of recreation, turned aside to give particular attention to one specialty. The narrow specialist outlook he could not abide.

The Ireland in which Wheeler was born in 1879 was a more than usually distressed country. To use the words of a historian of the period, during those late 'seventies it "rained outrages." But probably in the tall house in Merrion Square in which his father—who was also a William Ireland de Courcy Wheeler, and, like his son, reached the presidency of the

oyal College of Surgeons in Ireland—practised his profession in shadow of the political disturbance fell upon his childhood. His part of Dublin was still fashionable, the most elegant spectacle in its streets being the high-stepping horses of the Dublin doctors. William was educated at Trinity College, Dublin, where in 1899 he took honours in anatomy, natural science, and experimental science. He completed his education at the University of Berne and qualified in Dublin in 1902. In the following year the medal of the Dublin University Biological Association was awarded to him for a paper on "Deaths under Chloroform," possibly his first published work. He was appointed demonstrator and assistant to the professor of anatomy at Trinity College. Choosing surgery as his field he became F.R.C.S.I. when still only 26 years of age. It was at this time, in his twenties, that an unfortunate accident befell him, as the result of which he lost an eye. He overcame this disability, and although he was prevented from taking up golf, other people at least were not conscious that he suffered from any handicap in his professional work.

In 1904 he joined the staff of Mercer's Hospital, a famous Dublin charitable foundation 200 years old, to which he was attached for 28 years and was senior surgeon when he retired. He served a number of hospitals in Dublin and district—Kilkenny, Arklow, and Newcastle Hospitals, the Rotunda, and the National Children's Hospital. During and after the last war, in addition to his work abroad, he was honorary surgeon to the Forces in Ireland, donor and surgeon of the Dublin Hospital for Wounded Officers, and consulting surgeon to the Ministry of Pensions. He interested himself in hospital policy, advocating the amalgamation of the smaller hospitals, and also in nursing, being chairman of the City of Dublin Nursing Institute.

Among his manifold activities were those of external examiner to the National University and to Queen's University, Belfast, and, on this side of the Channel, to Edinburgh and Glasgow Universities; inspector of examinations for the Medical Registration Council of Ireland, and lecturer in surgery to postgraduates in the University of Dublin. In 1922 he was appointed surgeon-in-ordinary to the household of the Lord Lieutenant. He was consulting surgeon to the L.M.S. Railway and to the Orient Steam Navigation Company, and a member of the Departmental Committee on Workmen's Compensation.

In the scientific proceedings of the Royal Academy of Medicine in Ireland he took a conspicuous part and was president of its Surgical Section. A body in which he was also very much at home was the Irish Medical Schools and Graduates Association, of which he had been president. Soon after coming to London he became chairman of the Marylebone Division of the British Medical Association, and a year or two later president of the Metropolitan Counties Branch, probably the only instance of the same man having been president of an English and of an Irish Branch, for he had been president of the Leinster Branch in 1925-6. When the Association met in Dublin in 1933 he was president of the Section of Orthopaedics, and he was vice-president of the Section of Surgery at the Winnipeg Meeting in 1930 and at the Centenary Meeting in 1932.

With America he had many affiliations. He visited Crile's clinic in Cleveland, and, on at least four occasions, the Mayo Clinic in Rochester, and the brothers Mayo were his guests at his own clinic and private hospital in Upper Fitzwilliam Street. The Postgraduate Assembly of North America made him its president and an honorary member; he was also Honorary Fellow of the American College of Surgeons, a member of the consulting editorial staff of the American journal *Surgery, Gynecology and Obstetrics*, and a member of the American Editors' Association. He wrote well, with a concise—almost too concise—and original style. His *Operative Surgery*, which went into four editions, was first issued in 1918 in a form intended to be slipped into a medical officer's kitbag. His *Injuries and Diseases of Bone*, a collection of papers summing up his large experience in orthopaedics, appeared in 1928. He contributed many articles to our own and other journals and was a member of the editorial committee of the *British Journal of Surgery*.

On the outbreak of the present war he was appointed consulting surgeon to the Royal Navy in Scotland, with the rank

of surgeon rear-admiral. By road, sea, and air he travelled many thousands of miles on the duties this position entailed, and was welcomed wherever he went, not only for his surgical counsel but for his unfailing courtesy and kindness. The travel, although arduous, he probably enjoyed, because for forty years he had been a great lover of motoring. He once declared that he had suffered every tribulation which could befall the motorist, even to appearance in the police-court for a technical offence, but nothing abated his ardour.

Sir William de Courcy Wheeler married in 1909 the eldest daughter of the first Baron Craigmyle, better known as Lord Shaw of Dunfermline, a Lord of Appeal. They had a son and daughter. The son is now serving as an officer in the Gordon Highlanders.

A Naval colleague writes:

Sir William Wheeler had the great gift of friendliness and an irrepressible sense of humour, so that one rarely saw him looking unduly serious and never downcast. He was a tonic to his friends as well as his patients. Yet he had a keen sense of the implications of any problem with which he was confronted, while his surgical judgment showed a very nice discrimination of essentials, his operative technique was sound, and the results of his work, as might be expected therefore, were excellent. He was an inspiration to many a younger man, and out of his vast experience of surgical practice never tired of helping those younger and less experienced. Thoughtfulness for his patient was predominant in all that he did; as an example of this, only three weeks ago I watched him put a suture in a small incision he had made into a scrotum; he used a piece of silk-worm gut looped over a short piece of narrow tubing, and explained that when the suture was ready to come out all he had to do was to cut through the tube, into which one blade of a pair of fine scissors could be placed, and the patient would thus feel nothing of the cutting out of the stitch. Sir William was an indefatigable worker, very active right up to the last, and died suddenly in harness. A masterly paper on Syme's amputation and common derangement of the foot which he had written appeared only in April of this year.¹ Just over three weeks ago he had flown off to an emergency case in a fighter aircraft which made such a steep ascent from the aerodrome as to be described by some of the ground staff as "almost vertical." Sir William chuckled with delight at the memory of the experience. Not long afterwards he was climbing up a ship's side by a pilot ladder. He loved the Navy and was very proud to be serving as one of the consulting surgeons. It is distressing to think that those of us who counted ourselves privileged as his friends will no longer see his smiling countenance or hear any more of his wonderful stories. When an old woman patient of his met him a year or two ago she greeted him with, "Ah, Sir William, when you left Dublin the whole place shook." Many of us will feel with her that with his departure we have been badly shaken.

FRANK MARSH, C.B.E., Ch.M., F.R.C.S., who died at Alveley, Shropshire, on Sept. 12, was in his 89th year. He was born at Stafford and educated at King Edward's School, Stafford, and King's College Hospital. He qualified in 1877 and served with the Turkish Army in the Turco-Russian war of 1877-8. He was house-surgeon to the Stafford Infirmary and was for some years in general practice in that town and M.O.H. for 18 months. In 1886 he was appointed casualty surgeon to the Queen's Hospital, Birmingham, and was elected to the visiting staff in 1888, from which he retired after 15 years' service. He had become interested in the ear and throat specialty, then in its infancy, and was on the staff of the Birmingham Ear and Throat Hospital. He was president of the Section of Laryngology at the Annual Meeting of the B.M.A. in Birmingham in 1911, having previously served as secretary and as vice-president. For many years his opinion was much sought after throughout the Midlands, and he retained a large practice until the outbreak of war in 1914. He then commanded the First Southern General Hospital stationed at the University, and later became A.D.M.S. Birmingham District. After the war he devoted himself to the interests of the Red Cross and the County Territorial Association, and was awarded the honour of Knight of St. John of Jerusalem. He retired from practice in 1922 and spent the latter part of his retirement in Monte Carlo, but returned to England after the fall of France. In his opinions Col. Marsh was a staunch Conservative, though he took no active part in politics. He was devoted to country life and fishing, was of a gentle disposition, never uttering a harsh word. His elder son follows him as an ear and throat specialist in Birmingham.

The Services

Majors (Temp. Lieut.-Cols.) H. T. Chiswell and R. A. King, R.A.M.C., have been appointed O.B.E. (Military Division) in recognition of gallant and distinguished services in North Africa.

Group Capt. C. J. S. O'Malley, R.A.F., Wing Cmdr. H. L. Willcox, R.A.F., and Squad. Ldr. J. A. Mains, R.A.F.V.R., have been mentioned in dispatches.

CASUALTIES IN THE MEDICAL SERVICES

Died of Wounds.—War Subs. Capt. A. L. Thorp, R.A.M.C.

Prisoners of War.—Temp. Lieut.-Col. St. C. E. J. Barrett, R.A.M.C., War Subs. Capt. D. Christison, R.A.M.C., War Subs. Capt. H. W. Cowen, R.A.M.C., Lieut. E. J. Emery, R.A.M.C., Acting Major H. Henderson, R.A.M.C., War Subs. Capt. C. V. Lewis, R.A.M.C., Temp. Major A. T. H. Marsden, R.A.M.C., War Subs. Capt. J. R. Roulston, R.A.M.C., Lieut.-Col. E. MacA. Sheppard, A.A.M.C.

Wounded.—Lieut.-Col. K. H. Clark, R.A.M.C., War Subs. Capt. D. Rumney, R.A.M.C., Temp. Major A. F. Wallace, R.A.M.C.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there were large increases in the notifications of scarlet fever, 316, and dysentery, 109, but a fall of 312 in the incidence of measles.

There has been a rise of almost 50% in the notifications of scarlet fever during the past fortnight. During the week reviewed Yorks West Riding had an increase of 85 and Lancashire of 62. There was little change in the distribution of diphtheria and whooping-cough; one-fifth of the notifications of diphtheria were recorded in Lancashire. The fall in measles was general, the largest returns being in Lancashire 59, in Lincolnshire 49, and in Kent 45.

The notifications of dysentery were almost doubled during the week owing to large increases in existing outbreaks. The most important of these was in Leicestershire, Castle Donington R.D., where the cases rose from 4 to 36. Six administrative areas were involved in Yorks West Riding, where notifications rose from 13 to 43: Bradford C.B. 19, Harrogate M.B. 12. In Kent the cases went up from 13 to 24, eight areas being affected; Rochester M.B. had 9 cases. The outbreak of dysentery in Gloucestershire, Bristol C.B., which has persisted for five months, flared up, and 19 cases—an increase of 16—were recorded, bringing the total in the city to 217 for the past twenty-one weeks.

In *Scotland* there was a general rise in the incidence of infectious diseases, the only exception being diphtheria, the notifications of which fell by 20. Two areas were responsible for the increase of 41 in the notifications of dysentery—Dunbarton County with 28 more cases, and the city of Aberdeen with 19 more. The small general rise in scarlet fever continued, and the total went up by 42. In the city of Glasgow the figure for whooping-cough went up from 46 to 183, accounting for practically the whole of the increase of 151.

In *Eire* the only noteworthy change was a rise of 23 in the total for diphtheria.

In *Northern Ireland* there were 75 cases of scarlet fever, or half of these being notified in the city of Belfast.

The Week Ending September 11

The notifications of infectious diseases during the week in *England and Wales* included: scarlet fever 2,432, whooping-cough 1,751, diphtheria 700, measles 516, acute pneumonia 308, cerebrospinal fever 33, dysentery 201, paratyphoid 5, and typhoid 9.

Quarterly Returns for Eire

During the June quarter a birth rate of 23.4 per 1,000 was recorded, being 1.1 below the rate for the second quarter of 1942, but 2.5 above the average of the corresponding quarters of 1938-42. The infant mortality was 75 per 1,000 registered births, or 13 above the rate for the June quarter of 1942. The general death rate was 14.8, and was 0.2 higher than in the preceding second quarter. Pulmonary tuberculosis accounted for 978 deaths—33 fewer than in the June quarter of 1942 but 161 above the average of the second quarters of 1938-42. Other forms of tuberculosis caused 280 deaths—an increase of 22 on the June quarter of 1942 and 50 above the five-year average. Diarrhoea and enteritis was the cause of death of 245 children under 2 years of age; the five-year average is 133.

INFECTIOUS DISEASES AND VITAL STATISTICS

No. 3

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

A series of twelve weekly lectures on "The Psychology of Frustration and Fulfilment" will be given in Caxton Hall, Caxton Street, S.W., at 5.15 p.m. On Oct. 5, 12, 20, and 27 Miss Anna Freud will lecture on "Instinct Fulfilment and Frustration in Education." On Nov. 3, 9, 16, and 23 Miss E. N. Rooker (late principal of Dr. Barnardo's Staff Training School) will lecture on "Practical Application in Childhood." On Nov. 30, Dec. 7, 14, and 21 Prof. John MacMurray (London University) on "Social Sources of Frustration and Fulfilment." Tickets for the course, £1 (seats reserved until 5.10 p.m.), should be secured in advance from the Lecture Secretary, Provisional National Council for Mental Health, 39, Queen Anne Street, London, W.1. Single tickets (so far as accommodation permits) 3s. 6d. each. These lectures are especially addressed to those with social and educational interests.

The nineteenth Norman Kerr Memorial Lecture will be given before the Society for the Study of Inebriety on Tuesday, Oct. 5, at 4 p.m., in the Meyerstein Lecture Hall of the Westminster Hospital Medical School, Horseferry Road, S.W. The lecturer is Dr. A. Ninian Bruce and his subject is "Alcohol and Avitaminosis."

The annual general meeting of the Middlesex County Medical Society will be held at the Middlesex Guildhall, Westminster, S.W., on Tuesday, Sept. 28, at 5.15 p.m., when Dr. T. O. Garland will give an address on "Changing Medicine," which will be followed by a short discussion. Visitors, including members of the American and Canadian Forces at present in this country, will be welcome.

On Tuesday, Sept. 28, at 4.30 p.m. in the Council Room at Peter Jones', Sloane Square, Dr. J. Ramsbottom, Keeper of Botany, British Museum (Natural History), will give a talk on edible fungi, illustrated with coloured lantern slides.

A film of medical field work in the Russian Army will be shown at the Royal College of Surgeons of England, Lincoln's Inn Fields, on Friday, Oct. 8, at 4 p.m. Prof. S. Sarkisov will explain the main features of the film, and members of the medical profession are welcome to attend.

A series of lectures on national health has been arranged by the Royal Institute of Public Health and Hygiene, at 26, Portland Place, W., on Wednesdays, Oct. 13 to Nov. 17, at 3.30 p.m. Those wishing to reserve seats should apply to the Secretary at the above address.

The editor of *Transatlantic* satisfactorily answers all the questions that come to mind on seeing an entirely new periodical at a time when paper is severely rationed, and that is high praise from a contemporary. More than that, the first issue promises to achieve its object, which is to help the British public to a better understanding of American affairs and American life, but not by making propaganda. The material is presented objectively, even in the two articles on Mr. Cordell Hull and Senator Ball. Contributions like "What Geography does to America," "America and the Pacific," and "Who Speaks for America?" not to mention the excellent illustrations of "Small Town America," should do much to counter the impression engendered by the cinema that Hollywood is America. *Transatlantic* is an independent journal; it has no subsidy and is subject to no outside controls. Mr. Geoffrey Crowther is the editor, and it will be published each month by Penguin Books, Ltd., 110, St. Martin's Lane, W.C.2, price 1s. We have one complaint, and that is against the appearance of such a monstrosity as "beautician" in the caption on page 30 of the first number; it cannot be excused on the ground that it is copied from the illustration.

Manufacturers of insulin, in consultation with the Diabetic Association, have decided to standardize the colour and style of the packings so that in future type and strength will be uniform irrespective of maker. Steps have also been taken to eliminate unnecessary deterioration in pancreas during transit from cold storage to manufacturing plant. The number of diabetics in this country shows a yearly increase, and is now estimated at 200,000, but they do not all take insulin. The Ministry of Supply states that adequate supplies of insulin have been ensured both for the home market and for liberated countries.

The Ottawa Correspondent of the *Times* reports that the Dominion Government has approved expenditure for establishing plants and equipment in Montreal and Toronto for the production of penicillin. The appropriation just made will cover the cost of creating the industry and that of the production of the first 26,000,000,000 units of penicillin for use by the Canadian armed Forces. The new industry, employing 250 men and women, will come into operation next February.

Dr. Elliott Proctor Joslin, the eminent authority on diabetes, has been awarded the Distinguished Service Medal of the American Medical Association.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the Journal and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Attilage Westcent*, London; SECRETARY, *Medisera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Bismuth for Threadworms

Q.—Treatment of oxyuriasis by bismuth meal would appear to be the best course, since the bismuth, by finding its way into every saccule and crevice of the intestine, is able to reach the immature forms in the duodenal mucosa; whereas other remedies, like gentian violet, only exert their effect in the caecum. But there is great variation in the dosage recommended. One authority suggests giving 1 to 1½ oz. bismuth to a child of 5, and 2 oz. to older children; the meal to be repeated once a week for 3 or 4 weeks. At the other extreme I find a dose of 20 gr. i.d.s. recommended for adults. Now what is the optimum dose? How many doses are needed for a cure? And, in the case of the larger "meals," how are they best administered?

A.—Infestation with threadworms may be treated with bismuth oxycarbonate 120 gr. stirred up in water. A second dose is taken three hours later and a purge—e.g. calomel—is given at night. The process is repeated the next day. The dose for children from 7 to 15 years is approximately three-quarters of the above. For children under 7 it is half the adult quantity. Strict accuracy in the dosage of bismuth given by mouth is quite unnecessary because the drug is not absorbed. Diphenan or phenothiazine treatment is much more efficacious, though with the latter drug the danger of toxic effects is considerable.

Tremors: Diagnosis before Treatment

Q.—What is the diagnosis, prognosis, and treatment in the case of a man aged 69 years who has intention tremors and fasciculations of his arms and hands. He has none in repose, no rigidity, festinant gait, or mask facies, is able to exercise freely, and his mentality is normal. The symptoms were at first more in the left than right arm and hand, but have gradually in the course of years become so bad that he cannot now raise a cup to his lips steadily and has trouble in shaving with a safety razor. Any excitement makes matters much worse, and he feels trembling all over. He has taken phenobarbitone on occasions, but does not think it gave him much help.

A.—It is quite impossible to make a diagnosis here, for it would depend upon observation of the nature of the abnormal movements and the elicitation of physical signs of abnormality in the central nervous system, which must certainly be present. Most involuntary movements are made worse by excitement and eased by repose, and many of the conditions which give rise to involuntary movements late in life are progressive, so that it would be foolish even to hazard a diagnosis. The differential diagnosis would include arteriosclerotic Parkinsonism, cerebellar atrophy, olivo-fronto-cerebellar degeneration, and many of the degenerative processes which affect the basal ganglia. This is the kind of case where an expert diagnosis is essential before prognosis and treatment are discussed. I suggest a second opinion.

Frigitidy

Q.—A married woman aged 31 is complaining of loss of sexual desire and coldness towards any form of sexual intercourse. Her periods are normal. She has one child aged 2 years and is happily married. Stilboestrol seems to have no effect. In the male I have treated this sort of case with testosterone propionate and with success, but I should like advice regarding treatment in the female.

A.—The condition is probably psychological, and might respond to psychotherapy. Testosterone therapy in the female tends to stimulate libido by increasing the size and sensitivity of the clitoris, but large doses over a long period produce hirsutism. Incidentally, though testosterone is useful in the male suffering from organic hypogonadism, it is of no value for psychological impotence.

Noises in the Ear

Q.—What is the physiological explanation of the sound occasionally heard in the middle ear resembling a distant steam whistle? It is observed mostly in healthy persons while resting awake, or reading, or bed at night.

A.—It is not clear what is meant by "heard in the middle ear." The middle ear is a mechanism for collection, conduction, and transmission. The perceptive apparatus is in the internal ear, and noises originating therein either from some vascular disturbance or other lesion is generally of high pitch, sometimes corresponding to a lack of fork double vibrations. Tinnitus from middle ear lesions is generally more humming in character and is often compared to sound produced when a shell is held to the ear. The sound described, if entotic, originates in the internal ear.

Pruritus Ani

Q.—It is my impression that pruritus ani has increased in frequency lately. I have now five cases under my care. Palliative treatment, e.g., application of paraffin ointment—give intermittent relief. I should be grateful for a summary of practical measures likely to be helpful, and especially for an opinion as to the value of ray treatment. Though one case has a considerably enlarged prostate, it is certain I have been ruled out and none shows glycosuria. All are in middle age, and in all the occupation is sedentary.

A.—The patient should cleanse the anus after defaecation with wet and then dry cotton-wool, or, if there is much eczema, with cotton-wool and liquid paraffin or other bland oil—not with paper. He should then apply zinc cream with the addition of either benzocaine 2%, 1 g. pure carb. 12%, ol. menth. pip. 1%, phenol 1 g. 2%, or paroxytol 0.2%. Some prefer a dusting powder such as zinc and zinc oxide, equal parts. The cream may be applied also at night and whenever required. Benzocaine acts as an irritant to a few patients but is usually helpful. X-ray treatment, 100 r weekly (80 to 100 kV, unfiltered) for 2 to 6 times, with 8 as a maximum, is extremely useful. The intervals between doses may be increased to 2 or 3 weeks towards the end of the course. Painting the perianal skin with thorium X, 1,500 electrostatic units in 1 c.cm. varnish, is a useful measure when x rays are not available. Thorium X must be used on the day and approximately at the time for which it is ordered. The painting may be repeated every 2 or 3 weeks as required. Injections of procaine are sometimes useful, but the technique of injection is important and the injections must be placed alongside the anal canal as well as under the perianal skin. If good anaesthesia is produced it may interfere for a time with perfect sphincter control. Phenobarbitone $\frac{1}{2}$ to 1 gr. at bedtime is often useful.

Vitamin C Deficiency in Peptic Ulcer

Q.—Is there any evidence of a vitamin C deficiency in peptic ulceration? Should ascorbic acid be administered to those patients on a strict peptic ulcer dietary, or is this inclined to stimulate the gastric secretion?

A.—Vitamin C deficiency has been detected in a number of patients with peptic ulceration, particularly if they are on a strict diet. The peptic ulcer patient is denied fruit and coarse green vegetables, which are excellent sources of vitamin C, and milk, eggs, shops, bread, and fish contain very little vitamin C. For example, 2 pints of boiled or pasteurized milk will supply only from 5 to 12 mg. of vitamin C daily (minimal requirements 30 mg.). Platt (*Lancet*, 1936, 2, 366) describes four cases of scurvy resulting from strict adherence to special diets. The patients suffered from haematuria, purpuric rashes, epistaxis, and bleeding gums, all of which cleared up after administering vitamin C. In view of the importance of vitamin C in wound healing, and possibly for the integrity of the capillaries, patients with an active peptic ulcer, haemoptysis, and melæna of gastric origin should be given additional vitamin C to assist the healing process—e.g., 500 to 700 mg. daily—until there is a sharp rise in the urinary excretion of vitamin C, and then a maintenance dose of 50 mg. t.d.s. Vitamin C (ascorbic acid) can be administered with safety to patients on a strict peptic ulcer diet, as it does not stimulate gastric secretion in the doses given. It may be given powdered with the milk feeds. The milk serves to dilute the acid and has an excellent buffering action.

Treatment of Neurosyphilis

Q.—I have been treating for the past year a case of neurosyphilis, but with no result. I have been using a preparation of bismuth tryparasamide and am anxious to find out if there are any better preparations.

A.—It is not stated what is the stage or type of neurosyphilis, whether symptomatic or asymptomatic, or what are the changes in the cerebrospinal fluid. An early case of meningovascular neurosyphilis usually reacts well to trivalent arsenicals and bismuth as given for primary or secondary somatic syphilis; on the other hand,

in parenchymatous neurosyphilis tryparasamide and bismuth should be given a thorough trial. Assuming that this has been done, and the patient has active symptoms which are getting worse, and that there are marked changes in the cerebrospinal fluid, "artificial fever" seems to be clearly indicated. For this there are two main choices: (1) the use of one of the various fever cabinets; (2) induced malaria. In view of the difficulty of obtaining the use of a cabinet in this country at the present time the latter is recommended. At least 12 paroxysms should be provoked, and this should be followed by further chemotherapy with tryparasamide and bismuth. The danger of the treatment should be explained to the patient, who should be carefully examined as to his fitness to stand so drastic a procedure. The treatment would of course have to be carried out in hospital and by an expert; application for the necessary material for inoculating malaria should be made to the Ministry of Health.

LETTERS, NOTES, ETC.

Treatment of Lid and Corneal Burns

Dr. W. L. PEACOCK (Slough) writes: For nearly two years I have been treating these burns by placing 3 to 5 gr. of ordinary sulph. anilamide powder directly into the conjunctival sac. The effect in 24 hours on a neglected burn with chemotic conjunctiva and infiltrated cornea is miraculous. I plaster any external lid burns with more of the powder with the flat of a scalpel and apply a plain gauze pad and shell. The treatment is applied daily. There is no pain and only passing and slight discomfort. More healing takes place in a night than in a week of hot bathing, though I use this in conjunction. I think symblepharon is often prevented by this treatment.

Intermittent Claudication

Dr. JAMES MENNELL (London, N.W.1) writes: I wonder if the answer to the question about intermittent claudication (Aug. 21, p. 254) need have been "A large number of these cases are not true claudication at all, but a pseudo variety from which unless marked arterio-sclerosis is present, as in the patient mentioned on the next page under the heading "Painful Legs in Elderly Diabetic." The pseudo variety is often due to loss of elasticity in the structures of the calf, and, if so, by raising the heels—and it often requires a 24-in. elevation—the ambit is increased very materially and pain and discomfort decreased to a negligible degree.

Treatment of Schizophrenia

Dr. HENRY ROBINSON writes: Substantially my experience confirms the reply given to the questioner ("Any Questions?" *Journal*, Aug. 7, p. 189) quite naturally puzzled over the treatment of schizophrenia. The absurd and exaggerated claims made by medical writers in the lay press (and even at times in the medical press) regarding the high rate of "cure" of this disease under electric convulsion treatment have been responsible for much misapprehension among the public as well as among doctors. The facts are that no form of convulsion therapy has any lasting effect: in very early cases it sometimes produces temporary improvement in behaviour (e.g., intentional urination and defaecation into clothing and bed may cease) and it is fairly common for appetite to improve for a time—both electric and cardiazol shocks can do this; but the benefit practically never lasts. In very rare cases a prolonged intermission happens; but as this can anyhow be expected in a small proportion of early cases, it is very doubtful how far the treatment is the cause of it. Narcosis is never of any value and should not be advised for schizophrenia, though it has, of course, a distinct place in the treatment of some other psychoses, as has also convulsion therapy.

The Compressed Curriculum

At the time of going to press with the review of the arrangements for the new session at medical schools (Sept. 4, p. 307) particulars from Westminster Hospital and King's College were not available to us. We are informed that Westminster Hospital Medical School has been able to provide increased clinical facilities at Westminster Hospital by opening more beds for general medicine and surgery and by re-establishing the maternity and paediatric units. In addition the maternity unit at Ripley is in full working order, and at Staines instruction is given in medicine, surgery, and pathology. King's College has returned to London, and pre-clinical and clinical students are able to meet once again and the clubs and societies of the Students' Union are showing great activity.

A Difficult Skin Case

Dr. E. A. MOORE writes with reference to the question and answer published under this heading on Sept. 4 (p. 317): I should advise a trial of azochloramine. It has cleared up my own foot trouble.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 2 1943

A PROSPECT IN THERAPEUTICS*

BY

Sir HENRY DALE, G.B.E., M.D., P.R.S.

One of the clear impressions left by my student days in hospital, at the beginning of the present century, is that of surprise and disappointment at the lack of conviction, and even of interest, which our teachers showed in medicinal treatment, in contrast to the care and enthusiasm which they devoted to diagnosis. I suppose that before I entered the wards I had assumed, with the world at large, that a correct diagnosis would regularly enable an appropriate and effective remedy to be applied. It was disappointing to discover that this was so rarely the result, and that treatment would so often be prescribed with no better hope than to make the patient easier by alleviation of his symptoms, leaving Nature to deal, if possible, with the cause of the trouble. It is clearer to me in retrospect than it was at the time that there were very few remedies then which were even expected to deal with the causes of disease; for knowledge of those causes was itself a new thing, though it was beginning to come in a flood from the fresh outburst of experimental medicine in the last quarter of the nineteenth century. I think, indeed, that the period which I thus recall probably represented about the low-water mark of interest and confidence in the remedial value of drugs. Some of the established remedies for symptoms were clearly invaluable for their own purposes—digitalis, for example, morphine, cocaine, the bromides, and the general anaesthetics. The same was true of the use of salicylates in acute rheumatism, though it was not clear whether this dealt with the symptoms only or with the cause of the disease; nor can it be so even now until the cause of acute rheumatism is established beyond doubt. There were, indeed, a few drugs even then in use of which we can say, in the light of present knowledge, that their remedial value was due to action on the infective causes of the diseases in which they were used—cinchona and quinine for malaria, ipecacuanha (though not yet emetine) for dysentery, mercury and the iodides for syphilis. But at that time the knowledge of the malaria parasites was almost a novelty, the dysenteries were imperfectly differentiated, and the discovery of the spirochaete of syphilis was still in the future. The use of these remedies, like that of so many others, was then still based on the tradition of past centuries.

Emergence of Remedies of New Types

Out of the experimental researches which were bringing to light the causes of disease, and thus weakening the credit of drugs which could do no more than modify or alleviate symptoms, there were emerging, on the other hand, remedies of new types—not drugs unnatural to the body, but natural principles which would directly repair its deficiencies, or would supplement and reinforce its protective responses to infections.

One brilliant example was already available of each of these two types of natural medication. These were the treatment of myxoedema and cretinism with thyroid gland substance, and the treatment of diphtheria with the specific antitoxin. Here, beyond doubt, were remedies dealing directly with causes; and it was very clear that the physician ordered these with a confidence in their efficacy that contrasted strongly with the vague hope of indirectly helping the curative action of Nature, on which so much of the older therapeutics seemed to depend. It was in this direction only, in the provision of such natural remedies for deficiencies and infections, that a prospect seemed then to be opening for a new therapeutics dealing with causes; and researches in a range of the sciences allied to medicine have indeed gone far beyond any prospect then visible, in providing the wealth of hormones, vitamins, and immunological remedies which are now available. These alone would have effected a therapeutic revolution; we have only to recall the treatment of diabetes without insulin, of pernicious anaemia without liver extract, of rickets without vitamin D, or, for those whose memories extend so far, of diphtheria without antitoxin, to recognize its magnitude. At the beginning of the century it might well have seemed, on the other hand, that the prospect of advance open to the older therapeutics, which used drugs and chemicals unnatural to the body, and to a pharmacology then concentrated on attempts to analyse the effects of these, would be limited to the discovery of new and perhaps better remedies for the alleviation of symptoms. This, indeed, has been achieved, and with an almost embarrassing profusion. But the prospect was not to be thus limited. Even before this century began, the idea of a new type of therapeutic enterprise, aiming by deliberate experiment at the discovery of new artificial remedies which would deal directly with the causes of infection, had already begun to germinate. The results of this undertaking, as we can see them to-day, figure at least as prominently as the discovery of the natural remedies in the tremendous change, since the beginning of the century, in the very objective as well as in the achievements of medicinal treatment. I invite you to consider with me, in brief review, the steps leading to the present position, and the prospect now visible of a more regular and ordered advance in this quest for new and specific remedies for infections, called "Chemotherapy" by Paul Ehrlich, the man of genius who first undertook it and led the way to its first achievements.

As long ago as 1891, just when antitoxins were being newly discovered, Ehrlich had already seen that some of the parasitic causes of infection then coming to knowledge in such an imposing sequence did not evoke any rapid or effective reaction of immunity. He himself was also then engaged in experiments on antitoxins and antigens, and for another decade he was to lead the world in researches which gave to these their practical applications; but he had seen that along those lines there was nothing in view for the treatment of malaria, for example. The use of quinine had provided one of the few historic examples of a remedy which was dealing with the parasitic cause of an infection long before this was known. But, as Ehrlich was apt to complain, although the parasites causing malaria were now well recognized, pharmacology could still offer only data about the action of quinine on frogs'

* The Frederick Price Lecture delivered to the Royal College of Physicians, Edinburgh, on July 2, 1943.

muscle or on the mammalian nervous system, and nothing really relevant to its practical value in banishing the malarial parasites from the patient's blood. He embarked on a direct attempt to find a remedy for malarial infections better than quinine. He had been one of the first to use the aniline dyes in medical research, and had made extensive studies of the selective staining action of methylene blue. Since this dye stained the malarial parasites, and was not very poisonous for the higher animals, he was led to try it as a substitute for quinine. He obtained no more than a hint of success; methylene blue was certainly not better than quinine; but in that early observation was the germ of the method of research which he was later to call Chemotherapy. It is of interest, further, to note that when at length, many years after Ehrlich's death, the experimental use of malaria-like infections of birds led to the discovery of artificial remedies for human malaria itself, the structural analogy of methylene blue rather than that of quinine provided the point of departure for trials which led to success.

Dyes and Analogous Substances

When his studies on toxins and antitoxins were drawing to a close Ehrlich returned to this search for artificial remedies which would thus act directly on the causes of infection. The researches of Laveran and Mesnil had by this time brought to notice much more suitable conditions for such experimental work, in the use of trypanosomes which, unlike the parasites of human malaria, could be transmitted and retransmitted in indefinite series to small animals, such as rats and mice. Here were large actively motile protozoa, readily visible in a drop of blood under a moderate power of the microscope. It was easy to watch the effect on them of substances to be tested for curative action, to see whether the trypanosomes were stained by these if they were dyes, whether, in any case, their motility was abolished or impaired, and whether a treatment caused them to disappear from the peripheral blood of an infected animal. Early in these studies Ehrlich and the Japanese bacteriologist Shiga, who was then working with him, found a benzidine dye, which they called trypan red, that would

FIG. 1.—Trypan red

stain the trypanosomes with which they were working, and would banish these from the blood of mice heavily infected with them and bring to an end an infection which, if untreated, was progressive and uniformly fatal. This, the first experimental success of the new method of approach to therapeutics, has a personal interest for me in that it was just coming to completion when I myself was privileged to enter Ehrlich's Institute in Frankfurt for a short period, in 1903. I do not think that anybody, except perhaps Ehrlich himself, foresaw at that time what the future might hold of development from this small beginning.

Trypan red had not itself a real success in practical therapeutics; neither in man nor in large domestic animals would it deal with natural trypanosome infections as it had dealt with the very acute artificial infections of mice and rats. It did provide, however, the starting-point for a series which reached the peak of its achievement, so far, in the production, many years after Ehrlich's death but under the inspiration of his former pupil Hermann Roehl, of the complex substance known first as "Bayer 205," and later as "germanin," "antrypol," and "suramin," the last being the unprotected name adopted for general use by the *British Pharmacopoeia*.

FIG. 2.—Bayer 205 (germanin, suramin, etc.).

This is a colourless substance, but in structure and substantive properties resembles the dyes, and is a remedy of real value. After trypan red, French workers had produced other dyes with remedial actions on infections with trypanosomes—trypan blue and afridol violet; and the latter, though not a practical success

in itself, contained already the central urea-linkage which characterized the structure of the later Bayer 205 (suramin).

The line of research which started with the benzidine dye trypan red, had thus led to one clear practical success; it had made a contribution of much wider importance to the future of this newer kind of therapeutics in the knowledge which it had afforded incidentally concerning the mode of action of some of these artificial remedies for infection Ehrlich had, as was usual with him, picturesque concepts of the mode of action of these curative substances. He thought of them as magic bullets, flying unerringly to the object and avoiding anything else in their path. Their specific affinity must at least be strong, he maintained, for the infective parasite, and weak or wanting for the cells of the infected subject—they must be maximally parasitotropic and minimally organotropic; and he attributed this selective affinity to possession by the protoplasm of the parasite, and the absence from or paucity in the body cells, of "chemoreceptor" groups with which the curative substance would specifically combine. The action of an effective chemotherapeutic remedy, when fixed, he had thought of as a direct and rapid killing of parasites, in a dose still harmless to the cells of the host. It has become, in fact, very doubtful whether the action of a successful chemotherapeutic agent conforms to this simple type. When Ehrlich and his co-workers watched the action, trypanosomes swimming in diluted blood, of a dye which rapidly cured mice of an infection by the same species of trypanosomes, the effect observed was not of this directly lethal type. The organisms were seen to be stained by the dye, their motility was unaffected, and the period of their survival under the artificial conditions was not perceptibly reduced. When these stained and apparently still vigorous trypanosomes were injected into a normally susceptible mouse no infection followed. Ehrlich interpreted this observation as showing that the dye, while leaving the contractile activity of trypanosomes unimpaired, had stopped their power of multiplication, so that when they were injected into the mouse they died without reproducing themselves, and no infection was established. At the time when it was first put forward might well have been regarded as an explanation of opportunist type, improvised to meet an observed anomaly. With trypanosomes it could not be put to the test of a critical experiment, since there is no method even yet available for inducing these parasites to multiply in artificial culture. Nevertheless subsequent evidence obtained with organisms of other types has abundantly confirmed this speculative idea. There can now be no doubt, I think, that a large proportion of chemotherapeutic cures are, in fact, produced in this way: that the infection is brought to an end by stopping the further multiplication of the parasites, rather than by killing them outright; and it will be convenient to mention at this point one of the observations in which this mode of action is directly demonstrated.

During the last war it was found by Dobell and myself that the visible action of emetine on the vitality of *Entamoeba histolytica*, during the limited period of its survival in a saline suspension after removal from the infected bowel, was remarkably weak. To immobilize and visibly to kill the amoebae under these conditions a concentration of emetine was required many times greater than any which the human body would tolerate. By contrast, a derivative of emetine—demethoemetine—which was much more toxic for the amoebae in suspension and much less toxic for man, was found by Dr. Carmichael Lowe to be devoid of curative action in cases of amoebic dysentery which yielded normally to emetine. It was clear that observation on surviving amoebae, made under such conditions, gave no measure at all of the therapeutic action of the substances tested. One of the possibilities which we considered was that the curative action of emetine might be due not to such outright killing of the amoebae, but to suppression only of their growth and reproduction. It must be admitted that this had not seemed to us then to be very likely, but when Dobell and Laidlaw later devised a really good method for maintaining *Entamoeba histolytica* in artificial cultures it became possible for them to test a number of substances directly for their power to stop the multiplication of the amoebae. It was then revealed that emetine and its lower homologue, cephaeline, had a pre-eminent activity

his kind, corresponding to their unique value, among alkaloids of that series, in curing amoebic dysentery; while, by contrast, he derivatives, like demethoxyemetine, which had appeared to have a more potent immediate action on the vitality of individual amoebae but had failed to cure the infection in man, failed altogether to stop the growth of cultures when applied in the high dilutions at which emetine was still effective.

Arsenical Compounds

Another important line of chemotherapeutic research had started in 1905 with the observation by Thomas and Breinl, in Liverpool, that an organic derivative of arsenic acid, which had been marketed under the trade name "atoxyl," had a significant curative action on trypanosome infections in small rodents. Ehrlich then discovered, with Berthelm, in 1907, the true structure of atoxyl, as *p*-aminophenyl-arsonic acid:

FIG. 3.

With Roehl he added, in 1909, the very important observation that atoxyl itself had little visible effect on trypanosomes outside the body, but that the arsenoxide produced from it by reduction, in which the pentavalent arsenic was reduced to the trivalent arsenous form, was rapidly lethal for them in high dilutions. Following these clues, and widening the biological scope of the quest to include pathogenic spirochaetes as well as trypanosomes, he ultimately arrived with his Japanese co-worker, Hata, at the earliest major triumph of what was then (1910) still the new research method of chemotherapy, in the discovery of salvarsan (arsphenamine), with its revolutionary effect on the treatment of syphilis and other spirochaetal infections.

My concern, however, is not with the now familiar record of this practical therapeutic achievement but rather with what could be learned from the actions of atoxyl, salvarsan, and related substances, such as the later tryparsamide, as to the nature of the chemotherapeutic process. Salvarsan, an arsenobenzene derivative, has its arsenic in the trivalent form, but in a stage of reduction beyond that of the arsenoxide. Ehrlich's co-workers tested its directly lethal action on spirochaetes, using the soluble derivative neosalvarsan, which can be applied in a solution of neutral reaction, and found that here again the motility and visible signs of vitality of the organisms were unimpaired, though again they failed to produce infection if they were injected into a susceptible animal after they had been so treated. We might suppose, as Ehrlich had suggested in the case of trypanosomes treated with dyes, that the action of salvarsan had been to deprive the spirochaetes of the power of reproducing themselves, without directly and immediately destroying all their vital properties.

We have seen, however, that reduction of the pentavalent arsenical group of atoxyl to the trivalent condition, producing the corresponding arsenoxide, made it immediately and intensely lethal for trypanosomes; and the same is true of the most important of these pentavalent arsenicals, the later-introduced tryparsamide. Now if the arseno-compound salvarsan is partially oxidized, so as to produce two molecules of the corresponding arsenoxide, the same appearance of an immediate

FIG. 4.

intense toxicity for trypanosomes or spirochaetes is observed. For salvarsan (arsphenamine), therefore, as for the pentavalent arsenicals, there was a likelihood that the curative action observed after injection into a man or an animal suffering from a trypanosomal or spirochaetal infection was due, not to the substance as injected, but to a much more active arsenoxide produced from it by a relatively slow process of partial oxidation or reduction, as the case might be. And this possibility was directly supported by experiments carried out by Voegelin and his co-workers, demonstrating that the

relatively slow effects of either the arsenic acids or the arseno-derivatives, in causing the disappearance of the parasites from the blood, began after a definite interval, which was not present before the onset of the much more rapid action which the corresponding arsenoxides produced in much smaller doses. So that we have available two quite different explanations of the apparent lack of activity, outside the body, of arsenical derivatives which are so effective against the same parasites *in vivo*: on the one hand, the therapeutic process may, as in other cases, be due to the suppression of the reproduction of the parasites, rather than to the immediate destruction of all their vital activities; and, on the other hand, these arsenicals probably act after conversion, by contact with the body tissues, into the directly active form, by partial reduction or partial oxidation, as the case may be.

These considerations may naturally raise the question why, if the action is in any case due to the arsenoxides, these should not be directly administered, rather than the substances from which the body will produce them slowly and after an initial delay. Ehrlich, be it noted, had the arsenoxide corresponding to salvarsan in his hands before he had salvarsan itself, which he produced from it by reduction. Why did he introduce this additional step in production of the remedy, and impose on the body, apparently, the task of reversing it? The answer, I think, is to be found in the fact that the arsenoxide is not only much more potent in its action on the parasites but also, and to an equal extent, more poisonous for the tissues of the mammalian or other infected host. It can therefore only be given in a small dose at one injection; and, though the effect of this against the parasites is immediate and powerful, the concentration of the arsenoxide in the body fluids falls so rapidly from this low, tolerable concentration to a level below that at which it is effective, that the action is as evanescent as it is powerful. Even if only a few parasites have survived this brief action, these can rapidly renew their multiplication and re-establish the infection when the impediment has been removed. And there comes thus to our notice another factor in an effective chemotherapeutic action, which has not always, I suspect, received sufficient attention—namely, the need for a sufficiently prolonged and continuous action. This need is almost implied in the conception of the process as essentially an arrest of the multiplication of the parasites rather than an immediately lethal action on them. What is required is not the sudden attainment of a concentration sufficient to kill most of the parasites, at the risk of a concomitant injury to the host's tissues, but the long-continued maintenance, of a much lower and safer concentration, just sufficient to suppress the propagation of the parasites, without harming the cells of the host.

It would seem reasonable, then, to attribute the special efficacy of salvarsan not to a special affinity for the parasites associated with the arsenobenzene structure but rather to the physical properties which enable it to form a depot in the tissues, or, perhaps, a film on the surface of the parasites, from which a steady low concentration of the much more toxic but directly active arsenoxide will be produced. Discussing this idea in a review, now some twenty years ago, I further raised the question whether the same result might be obtained by direct injection of the arsenoxide, if means could be devised for administering this by a slow, continuous infusion. Apparently this has now been achieved, and the hydrochloride of this precursor of salvarsan, which Ehrlich so long ago rejected as too immediately toxic, has, in fact, recently come into use in the U.S.A., and even more recently in this country, for intravenous administration by constant drip infusion, or by frequently repeated small injections, under the trade name "mapharsen," or "mapharside."

How the Action of Diamidines was Discovered

Hitherto the process of discovery of new therapeutic agents had been to a large extent empirical, involving the synthetic preparation and testing of a large variety of derivatives of some substance which had itself shown a promising degree of activity against some particular kind of infection. Such new starting-points have themselves, in notable instances, been reached with the help of theories which have had to be discarded. A striking example is provided by researches started

by Prof. v. Jancsó of Szeged, who set out to find substances which would deal with trypanosomes, not by killing them, or even affecting them directly, but by starving them out. So he treated the infected mice with decamethylene-diguanidine, which, under the name "synthalin," had been tried some years ago as a synthetic substitute for insulin. It had not been really successful for that purpose, but v. Jancsó found that it caused the trypanosomes to disappear rapidly from the blood of his mice, and naturally regarded this as confirming his conception of a chemotherapy based on depriving the trypanosomes of glucose by causing a disappearance of that substance from the

Fig. 5.

blood. Fortunately the late Prof. Warrington Yorke had the curiosity to test the matter for himself, and found that synthalin, applied even in extremely high dilutions, containing as little as 1 part in some 250 millions, would cause the death of trypanosomes in an artificial suspension in which there could be no question of its affecting the supply of glucose. And thus synthalin, the trypanocidal action of which had been discovered in a trial based on a completely erroneous hypothesis, became the starting-point of a new line of investigation, in which my former colleague Dr. Harold King and the late Prof. Warrington Yorke were led to the discovery of still more therapeutically potent and at the same time less toxic diamidines; and their discoveries led, in turn, to further developments in industrial laboratories which have given to therapeutics the substances called stilbamidine, which seems likely to establish itself as the most effective remedy for kala-azar yet produced, curing types of that infection in which antimonial remedies of all kinds had failed; pentamidine, which has proved to be effective in *Babesia* infections of cattle; and propamidine, which appears to be giving promising results even in the local treatment of certain bacterial infections of wounds. It is of interest to note that, as long ago as 1928, Staub and Küng had observed the powerful antiseptic action of synthalin, but regarded it as too toxic to have chemotherapeutic value.

Sulphanilamide and its Derivatives

The fact that v. Jancsó's conception, which led him to test the chemotherapeutic action of synthalin, had so little true relation to what he observed or to the discoveries which followed from the clue thus presented, should not prevent us from recognizing its essential novelty. He seems to have envisaged, for the first time, the possibility of a chemotherapy which eliminates the parasites, not by a direct action on them of any kind, but by depriving them of nutriment—not by a *Blitzkrieg*, or even by a war of attrition, but by a food-blockade. We shall see that this idea is not wholly unrelated to those which offer the most suggestive interpretation for one of the most recently discovered and probably the most widely recognized and celebrated of all chemotherapeutic actions—the action on bacterial infections of sulphanilamide and the growing family of its derivatives. The effect of introducing a sulphonamide ($-\text{SO}_2\text{NH}_2$) grouping into azo-dyes, in increasing the fitness of their staining properties for silk and wool, their "substantive" properties, probably led to the first use of such compounds for therapeutic effects on infections of bacteria, on the lines of Ehrlich's conception that the remedy must be fixed by the parasite to exert its lethal, curative action. For many years there had been no clear and unqualified success in this field of antibacterial chemotherapy, and the few had even become prevalent that chemotherapy was unlikely to provide a successful remedy for diseases due to bacteria, and that we should have to depend on immunology to produce specific remedies for these, in contrast to the success of chemotherapy, and the failure of immunology, in finding remedies for infections due to protozoa and spirochaetes. Even in this period of long delay, however, there were more promising signs for those who could read them. Morgenroth's discovery of the cure of experimental pneumococcus infections in mice by optochin, an artificial homologue of quinine, had led of practical application only because of an unforeseen toxic action of this alkaloid on a proportion of human patients.

Browning, during the last war, had discovered valuable antibacterial properties in acriflavine, an acridine dye which Ehrlich had earlier found to be effective in trypanosome infections of mice and had named trypaflavin in that connexion; but acriflavine and the simpler proflavine, while retaining their value as bactericidal agents for local applications, had not proved suitable for internal chemotherapy in the stricter sense. It appears, indeed, in retrospect, that the curative value of sulphanilamide itself might even have been discovered many years earlier, when Heidelberger and Jacobs, in New York, observed in 1919 that a sulphonamide derivative of the cinchona alkaloid cupreine had a potent antiseptic action on artificial cultures of certain bacteria. There was no practical development, however, of that observation; and the production of the red sulphonamide dye known as prontosil, a sulphonamide of the dye chrysoidine, by the German chemists Klarer and Mietsch in 1932, and Domagk's finding that this had a definite curative action on mice infected by an otherwise fatal injection of streptococci, was an essentially new discovery, and certainly one of the most important yet made in the short history of chemotherapy. Domagk published these observations in 1935, with the promising results of certain clinical trials of prontosil on cases of streptococcal infection in man. In the following year

Fig. 6.

Colebrook and Kenny, in London, completed an extended and carefully controlled clinical trial of its value, in a uniform series of cases; and the publication of their results first convinced the world that the discovery of prontosil and its action was an event of first-rate importance for practical therapeutics. Even while this trial was in progress, however, came evidence from Tréfouel, Nitti, and Bovet, in Paris, that sulphanilamide, a reduction cleavage-product of prontosil, was as effective against experimental infections as prontosil itself; and Colebrook and Kenny were thus able to confirm this finding also, and to extend it to the natural streptococcal infections of their series. And then it was found that prontosil undergoes this reduction cleavage in the body, giving rise there to sulphanilamide; it might be doubted, therefore, whether there was any ground for connecting the action of prontosil with its properties as a dye, or for regarding it as anything but a source of sulphanilamide.

When prontosil was tested on artificial cultures of streptococci, or of other organisms susceptible to its action *in vivo*, it had no effect upon them. Sulphanilamide, on the other hand, while it did not sterilize the culture in any reasonable concentration, stopped its growth in dilutions comparable to those which could be produced in the blood of the living patient. Here again, therefore, we have a case in which the substance originally administered was not chemotherapeutically active as such, and in which the direct agent, formed from it by action of the body tissues, produced its effect by stopping the growth of the infecting parasites and not by killing them directly—being in this instance "bacteriostatic" and not directly "disinfectant" in its action. There was not in this case, however, any clear advantage in administering the inactive precursor prontosil and allowing the directly active substance sulphanilamide to be formed from it as required; the cleavage proceeded so rapidly that the administration of the preformed sulphanilamide appeared to be practically equivalent.

From that point onwards the practical applications of sulphanilamide itself, and of the succession of more effective derivatives that have issued from the chemical laboratories of many countries, have been developed and extended with a rapidity new to experience. Week by week the medical press of the world has offered, and still offers, new evidence of the special value of one or another of these derivatives for the treatment of a particular type of infection; and the repute of their value has spread far beyond medical circles. There can be no doubt that their introduction has, in itself, transformed an important branch of curative medicine, or that the use of these substances by various methods, including that of

ical application, has changed the aspect of many of the medical and surgical problems of war. The prospect, however, of an ordered development of this relatively new field must certainly depend on the extent to which a clearer conception can be attained of the nature of the chemotherapeutic process itself; and a new promise of such insight was offered by discoveries which were just becoming ripe for record, when the outbreak of war again brought an interruption of so many researches of the type requiring patient concentration and the long view.

New Links between Chemotherapy and Biochemistry

The conceptions which spring from these recent discoveries, in contrast to those which were earlier dominant, attempt to interpret the action of a drug on an infecting organism in terms of a cellular biochemistry which was not available to the earlier theorists. As long ago as 1923 Voegtlin and his co-workers, in considering the mode of action of the directly active arsenoxides produced in the body from arspenamine and the other specifically curative arsenic derivatives, had pictured the arsenoxide radical as combining with the thiol radicals of glutathione in the protoplasm of the cells affected, and thereby interfering with their respiratory metabolism. In 1940 Fildes independently put forward a closely similar idea

FIG. 7.—Suggested mode of action of an arsenoxide (Voegtlin).

to explain the disinfectant action of mercury salts, suggesting that the mercuric ions combined with and inactivated the free thiol groups of bacterial cells. In both these investigations the suggestion was supported by evidence that reduced glutathione, or other substances offering free thiol radicals, injected into the animal or added to the culture medium, would neutralize the activities of arsenoxides and mercury salts respectively.

It will be noted that in both these cases the suggested action involved the fixation of the toxic agent to particular groups in the protoplasm of the affected cells; and to that extent the suggested thiol groups might be regarded as representing a type of Ehrlich's chemoreceptors in a chemically more definite form. Fildes, however, used his observation, and others which were being made in his laboratory, as the basis of a more general conception of the chemotherapeutic process, as essentially an interference with the action of some group or chemical factor required by the infecting organism for its normal life and growth. In such a generalized form this conception can be made applicable to the action of the sulphonamide derivatives on bacteria. There is no evidence, in this case, for any firm combination of the therapeutic agent with any group or constituent of the cells attacked. The chemoreceptor conception, in that original sense, is here not applicable. A sufficient concentration of the sulphonamide derivative must be maintained in the environment of the susceptible bacterial cells if their growth and multiplication are to be suppressed; and they begin to grow and multiply again as soon as the concentration falls below that minimum. We have then, apparently, not a combination but a labile antagonism to some substance or process needed for growth. Fildes referred to the substance, thus somehow put out of action, as an "essential metabolite," while others have spoken of a "growth factor" or pictured interference with an enzyme action. Further experiments gave a much greater precision to the idea. Stamp showed that a sterile extract of streptococci, added to the culture medium, would neutralize and nullify the bacteriostatic effect of sulphanilamide on the culture. Then Woods, in Fildes's laboratory, found that an extract of yeast would act similarly as an antagonist to the action of sulphanilamide; and, finally, he was able to identify the antagonistic constituent, to a high degree of probability, as *p*-aminobenzoic acid.

FIG. 8.

A casual inspection shows that the molecular configuration of *p*-aminobenzoic acid has a large measure of community with that of sulphanilamide. Woods accordingly suggests that the

mode of action of sulphanilamide is to pre-occupy some cellular enzyme, the normal function of which involves an action upon *p*-aminobenzoic acid as one of the essential steps in the growth-metabolism of the bacteria.

The hypothesis is attractively suggestive, and there is additional evidence in its favour. Woods found a fairly constant proportion between the concentration of sulphanilamide in a medium and the concentration of *p*-aminobenzoic acid which must be added to neutralize its bacteriostatic effect. He found, further, that the concentration of *p*-aminobenzoic acid required to abolish the effects of different sulphonamide derivatives increased with the bacteriostatic activity; sulphapyridine, for example, required a greater concentration to neutralize its effect, corresponding to its greater activity, than did sulphanilamide itself. It must be admitted, however, that an inspection of their formulae does not yet afford any suggestion why sulphapyridine should be more effective than sulphanilamide in pre-occupying an enzyme normally acting on *p*-aminobenzoic acid. Two other substances have already been detected in certain bacteria which similarly antagonize the action of sulphanilamide, and other attempts to find substances with bacteriostatic effects, attributable to similarities in molecular configuration with other known factors of bacterial growth, such as pantothenic acid, have already given results of promise. Whether these ingenious suggestions are confirmed by further knowledge or prove to be inadequate, I believe that they will have a permanent significance, as having brought the interpretation of a chemotherapeutic process for the first time into clear relation with a cellular metabolism which can be stated in terms of a known chemistry. I think that we are entitled to hope that chemotherapy may soon find that its means of discovery are no longer limited to the almost unselective trial of as many derivatives or analogues as possible of some substance which has shown an unexplained curative effect on a particular infection. A more fundamental knowledge of the conditions and factors required for the multiplication of the infecting organisms may give, at least, an invaluable direction and concentration of aim to the search for remedies. The bacteria, with the ready opportunities they afford for studying in artificial cultures the methods of supplying and interfering with their requirements for growth, or the factors promoting their pathogenicity, offer the most promising field as yet for thus exploiting the resources of biochemistry with a therapeutic aim. But it is tempting to speculate as to what the world might gain, for example, in the present emergency if means were available for growing the malaria parasites at the different stages of their complicated life cycles, under artificial conditions permitting factors requisite for their multiplication to be studied, as a guide to attempts to find other and better remedies than quinine—even better than mepacrine (atebrin), which has already come from one of the most brilliant and determined exploitations of the longer available methods.

Mycogenous Remedies for Infections

Meanwhile, we may note the creation and strengthening of another kind of link between biochemical studies and antibacterial therapeutics. Dubos, in New York, has trained a soil bacillus, by cultural restriction, to give a good yield of peculiar polypeptides having a high toxicity for certain pathogenic bacteria, one of them, gramicidin, being specific in its intense antiseptic action for the Gram-positive cocci. Much more brilliant, however, in its promise for the practical treatment of septicæmic conditions has been the recent progress in the purification and isolation of penicillin. After Fleming's chance observation of the production of this remarkable substance from a colony of *Penicillium notatum*, and his preliminary examination of its properties, and even of its therapeutic possibilities, in 1929, there was a long gap of years. Then, after the discovery of the action of sulphanilamide had shown the possibility of an antibacterial chemotherapy with agents of a low toxicity, the interest in penicillin was revived and rapidly extended by the work of Florey and his colleagues at Oxford. They showed how it could be extracted from a culture filtrate and purified so as to make it safe for intravenous administration; and they produced the first clinical evidence of its remarkable therapeutic possibilities. And now the chemists in Oxford and elsewhere are hot on the trail,

and manufacturing laboratories on both sides of the Atlantic are straining their resources in the attempt to make and to isolate penicillin, and to determine, perhaps, its constitution, or that of the penicillins if there should prove to be more than one active constituent. Then finally, perhaps, may come a synthesis of a penicillin, or of some simpler analogue with similar action. There seems to be a possibility, even a likelihood, that this remedy against infection from a new kind of source may approach, more nearly than any other yet available, to the ideal of toxicity for the infecting organism and complete absence of it for the patient. Here again, however, the effect on the organisms is merely to prevent their multiplication, and not to kill them outright. There can be little doubt that the first pages only are being turned, as yet, of a new and brilliant chapter in the specific treatment of infections.

Conclusion

If we are to form an idea of the prospect which I took as the subject of my lecture, I think that it is important to recognize how much of the change which I have been discussing has taken place in the latter part of the period covered by the survey—in the years, in fact, since the last war came to an end. This is not only true of the progress of chemotherapy, which I have considered in more detail, but equally so of exact knowledge of the natural remedies for deficiencies. At the end of the last war only one hormone, adrenaline, had yet been chemically identified, and no vitamins. It was still possible then to suggest of many of the hormones that their very existence was problematic, and that they, and the vitamins as well, might in any case be so labile and otherwise inaccessible that the methods of chemical isolation and structural study would never be applied to them. Yet before the present war broke out large and rapidly growing series of both hormones and vitamins had been isolated, identified, and made available for practical use by artificial synthesis; and a beginning had even been made of the discovery of simpler synthetic substitutes. In chemotherapy, though salvarsan had appeared before the last war began, there was still, when it ended, no clear prospect of further advance by routes which could be mapped on scientific principles. Wholesale and almost haphazard trial of derivatives or analogues of any substance which had shown a promise of activity seemed to be the only way open; the marvel was, and still is, that so much has been achieved by such methods.

I have tried to trace the progress since that time, from the picturesque but frankly empirical conceptions which Ehrlich had bequeathed, based apparently on his knowledge of selective staining with dyes and of the extreme specificity of immune reactions. From these ideas of magic bullets, bringing down only the parasites by virtue of a mysterious affinity for them alone, we passed to recognition of the effect as stopping their reproduction rather than slaying them outright, turning to their defeat the tide of battle with the host's natural resistance to infection. We came thus to the conception of the effect as usually a mild and persistent one, dependent for that persistence, in some cases, on affinity of the remedy for the host's tissues and not merely for the parasites. And, finally, we reached the conception, just emerging, of the nature of the effect on the reproduction of the parasites, stated in biochemical terms of the interference with known factors of their growth. Look back with me again to medicinal treatment at the opening of this century, and consider that the portentous change between then and now has been so largely an achievement of the years of uneasy armistice between two open wars, at a time when the full impact of research on practical medicine was only just beginning to be felt. Portentous, I said; but what does it portend? Does it not mean that, when we have won freedom from war and from fear of war, the prospect of further achievement in this field of experimental therapeutics, so newly opened to enterprise, is brilliant beyond anything that experience yet enables us to picture? What an opportunity, I am moved to exclaim, for those who still have the years before them in which to use it! I hope that it may fall to the lot of one of them, when the passage of years may justify another review, to tell again in one of these lectures how much of this present prospect has by then become a reality, and to survey yet further possibilities, beyond any that we can now imagine, which will then be coming into view.

CUTANEOUS AND CONJUNCTIVAL DIPHTHERIA

A SERIES OF CASES

BY

H. C. MAURICE WILLIAMS, O.B.E., M.R.C.S., L.R.C.P.
D.P.H.

Medical Officer of Health, and Medical Superintendent, Borouh
Isolation Hospital, Southampton

Medical literature records that cutaneous diphtheria was no uncommon condition in the nineteenth century, but now days it is so rarely recognized in this country that a series of cutaneous and conjunctival infections admitted to the Isolation Hospital, Southampton, seems worth recording. All the cases were admitted from a military hospital. Rolleston (1925) describing a large number of diphtheria admissions, found that approximately 1% showed cutaneous involvement, and Cameron and Muir (1942) reported a series of 66 cases occurring among troops in Palestine.

Details of Cases

During the eight months prior to April, 1943, there were admitted to the Isolation Hospital, Southampton, from a military hospital, 19 patients who had lesions of the skin or eyes from which *C. diphtheriae* had been isolated. Of these 12 were infected with virulent and 4 with avirulent organisms in the remaining 3 cases tests for virulence were not carried out.

The 12 infections with virulent organisms comprised: (i) 1 case of cutaneous diphtheria; (ii) 2 cases of cutaneous and conjunctival diphtheria; (iii) 3 cases of conjunctival diphtheria with associated skin lesions from which *C. diphtheriae* was isolated (one of these was also a faucial carrier); (iv) 1 case of cutaneous and faucial diphtheria. The avirulent infection were 3 cases of cutaneous infection and 1 of conjunctival infection. The 3 cases in which tests for virulence were not carried out were two of cutaneous and faucial infection, and one of conjunctival infection with an associated skin lesion from which diphtheria bacilli were not isolated. All 19 patients were males aged between 21 and 37 years.

Case 1.—Admitted to the military hospital for treatment of seborrhoea of the scalp and forehead and acute purulent conjunctivitis of four days' duration. An eye swab contained diphtheroid organisms. After two weeks the conjunctivitis became more purulent and a few days later bilateral keratitis was present. The eye was again swabbed, and was found to be infected with *C. diphtheriae* (gravis type I). When admitted to the isolation hospital bilateral conjunctivitis and keratitis were present. There were a dense opacity of the right cornea and an ulcer of the left cornea with hypopyon. No membrane was seen. Treatment consisted of 20,000 units of diphtheria antitoxin i.m., and bland irrigations to the eyes. The inflammation settled down in two weeks, leaving cornea with a frosted-glass appearance. Two months later the vision of the right eye was 6/18 and the cornea was moderately scarred, especially in the lower segment. The pupil was active, but posterior synechiae were present. The left cornea was extensively scarred and staphylocomatous in the lower quarter. Vision of left eye was C.F. at 6 in. only.

Case 2.—Admitted to military hospital with impetigo of face and ear. Skin swab reported positive five weeks after admission, but later reported avirulent.

Case 3.—Admitted to the military hospital with dermatitis affecting the "respirator" area. Two weeks later developed a sore throat, a swab from which proved to contain *C. diphtheriae*. A skin swab was also positive. On admission to the isolation hospital the dermatitis cleared up within a fortnight. 10,000 units of antitoxin were given, but later skin swabs showed the presence of diphtheroids only.

Case 4.—Admitted to the military hospital with purpura and pyoderma. A skin swab was reported positive for *C. diphtheriae* shortly before transfer to the isolation hospital, where on admission the patient was found to have an ulcer the size of a five-shilling piece on the outer aspect of the right thigh. The ulcer had a well-marked edge and a grey membranous slough covering its base. 10,000 units of antitoxin were injected, and sulphanilamide powder was applied after the ulcer had been soaked to remove slough. The ulcer healed in about two months.

Case 5.—Admitted to military hospital with impetigo of the face. Three weeks later a skin swab was found to contain virulent *C. diphtheriae* (gravis).

Case 6.—Admitted to military hospital with impetigo of the face and neck of four days' duration. Five days later he developed

conjunctivitis, and the discharge contained *C. diphtheriae*. The virulence of the organism was not determined.

Case 7.—Admitted to the military hospital suffering from impetigo of the chin of fourteen days' duration. Ten days later he developed bilateral purulent conjunctivitis. White membrane was seen on the edge and inside of the lower eyelids two days later. Swabs from eyes and skin showed the presence of *C. diphtheriae* (gravis). The patient was afebrile. At the isolation hospital 60,000 units of antitoxin were given and local treatment was applied to the eyes. Skin and eyes cleared up completely in about four weeks.

Case 8.—This man had impetigo of the face and neck, and two weeks after admission to the military hospital he developed rhinitis. A nasal swab was reported positive for *C. diphtheriae*, but the organisms were avirulent. After transfer to the isolation hospital skin swabs contained virulent *C. diphtheriae* (gravis type I), but throat and nose swabs were negative. The skin condition improved rapidly after the injection of 10,000 units of antitoxin.

Case 9.—Admitted to the military hospital with syphilis barbae. Three weeks later virulent *C. diphtheriae* (gravis type I) were isolated from the skin.

Case 10.—A case of impetigo of the face, neck, and left ear which developed a yellowish-white membrane on the skin behind the left ear one month after admission to the military hospital. A swab from this membrane was found to contain avirulent *C. diphtheriae*. At the isolation hospital only diphtheroids were found in swabs from the skin until one month later, when virulent mitis organisms were reported, presumably due to cross-infection. The skin healed in three weeks.

Case 11.—Admitted to the military hospital with seborrhoea capitis. Three weeks later conjunctivitis developed and virulent *C. diphtheriae* (gravis) were found in the purulent discharge. Swabs taken at the isolation hospital were negative, and the conjunctivitis soon cleared up. 20,000 units of antitoxin were given.

Case 12.—Eleven weeks after admission to the military hospital for treatment of impetigo this patient developed a mild purulent conjunctivitis. The discharge contained avirulent *C. diphtheriae*. At the isolation hospital eye swabs were negative, but throat and nose swabs were positive on two occasions within a week of admission.

Case 13.—Admitted to the military hospital as a case of impetigo, this patient was swabbed and found to have *C. diphtheriae* (gravis) on the skin, but the organism proved to be avirulent.

Case 14.—This man had impetigo of the chin and face three weeks before and a sore throat two days before admission to the military hospital. Throat and skin swabs contained virulent *C. diphtheriae*. The skin persisted positive after the patient had been transferred to the isolation hospital, but swabs from the throat and nose were negative.

Case 15.—This man had impetigo for one month before admission to the military hospital. Five days after admission he complained of sore eyes, and his left eyelid was found to be scabbed. A swab from the eye contained virulent *C. diphtheriae*. At the isolation hospital throat and nose swabs contained virulent organisms of the same type as those found in the eye.

Case 16.—Admitted to the military hospital with syphilis barbae of nine months' duration, this man two months later developed purulent conjunctivitis, and *C. diphtheriae* was found in a swab from the eye. The organism proved to be avirulent.

Case 17.—Five days after admission to the military hospital for treatment of impetigo of the face a blister appeared on one knuckle of this man's right hand. A slough developed, and was found to be infected with virulent *C. diphtheriae*. The infection persisted after transfer of the patient to the isolation hospital, and on two occasions virulent organisms were found in the throat and nose without clinical evidence of infection.

Case 18.—This man had impetigo for three weeks before admission to the military hospital. After two weeks' treatment only slight crusting remained. Following contact with cases which proved to be diphtheritic infections *C. diphtheriae* were found in throat and skin swabs.

Case 19.—After three months' treatment for impetigo in the military hospital a lesion thought to be keloid developed on the neck. A scraping from the skin contained virulent *C. diphtheriae* of gravis type. Swabs at the isolation hospital were all negative, and the skin healed quickly after diphtheria antitoxin had been given.

Commentary

General Features.—No toxæmias could be ascribed to the action of diphtheria bacilli in any of these cases. No paralysis ensued. Membrane was seen in three cases of cutaneous infection (in one of these the diphtheria bacillus isolated was avirulent) and in one conjunctival infection. In all the other cases the lesions had the usual characteristics of the skin condition originally diagnosed. The average length of stay in the military

hospital before transfer to the isolation hospital was four and a half weeks. The average in the latter hospital was six weeks.

Treatment.—In the isolation hospital diphtheria antitoxin was injected intramuscularly in every case. The other treatment was that usually given for the particular cutaneous or conjunctival infection.

Infectivity.—It is of interest to note that in addition to the 19 cases mentioned above there were admitted from the military hospital during the same period 18 other cases of diphtheria, including 7 of the staff. These 18 cases were faucial infections in all but one instance, the latter being a case of rhinitis.

Conclusion.—Recognition of cutaneous diphtheria among patients with a variety of skin infections suggests the need for more frequent bacteriological investigation of such cases.

ACUTE ALEUKAEMIC MYELOID LEUKAEMIA

BY

B. L. DELLA VIDA, M.D. Rome

AND

M. C. CONNELL, B.A.

(The Royal Hospital, Wolverhampton)

The occurrence of acute myeloid leukaemia in the aleukaemic phase during adult life is rare enough to make the following cases worth reporting.

Case I

A man 63 years old, a window-cleaner by trade, was admitted to the Royal Hospital on Sept. 13, 1942, with a history of a severe sore throat and difficulty in speaking for the past two weeks. These symptoms became progressively worse, and one week before admission he complained of severe malaise and generalized pains over the body; the temperature was then found to be 103° F. Five days before admission a haemorrhagic rash appeared on the legs and arms; this became purple after 48 hours. On the day of admission he complained of headache, shortness of breath, and stiffness of the neck. During the illness he became increasingly drowsy, but could be roused and was quite rational. He had been on a course of sulphamylamide (1 g. four-hourly) and vitamin C (150 mg. daily). Past and family history revealed no significant facts. Bowels and micturition had been normal; there was no loss of weight.

On admission the patient was very drowsy, but roused easily; temperature 102° F., pulse rate 94, and respiration rate 28 per minute. The legs showed a number of papulo-macular haemorrhagic spots with small yellow vesicular centres and irregular edges, located mainly over the shins; the size varied considerably, the largest being 1 cm. in diameter; there was no fading on pressure. The arms were covered with red indurated nodules larger than those observed on the legs, up to 2.5 cm. in diameter, chiefly localized around the elbow, resembling erythema nodosum and not showing the vesicular centre present in the leg lesions. There were also a few macular spots on the back and abdomen. The limbs presented cogwheel rigidity and the joints were very tender on movement. In spite of the increased respiration rate there was no clinical evidence of abnormalities in the respiratory system. Heart and vessels normal; blood pressure 120/70; spleen and liver not palpable; no glandular enlargement. Pupils and fundi normal; all reflexes normal; tongue and pharynx coated with dried mucus; breath fetid.

On the day after admission the patient developed herpes labialis, which later became haemorrhagic. Though remaining rational he became progressively more drowsy and dyspnoeic; the pulse rate rose to 120 and the respirations to 40 a minute. Death took place on Sept. 17.

The laboratory investigations carried out in the short period of time during which the patient was under observation showed: No abnormalities in the urine except a large amount of urobilin; haemoglobin, 62%; red cells, 3,940,000 per c.mm.; mean diameter of the red cells, 7 μ ; white cells, 2,800 per c.mm.—polymorphs 18%, eosinophils 1%, mononuclear cells 81%. Some of the mononuclear cells were typical lymphocytes, but the great majority were of primitive type: one normoblast was seen while counting 100 white cells; platelets in the films appeared to be very scanty.

At first sight the primitive cells were taken to belong to the lymphatic series; but on account of the presence of azur granules in the more immature forms it was decided to investigate the case more fully by means of sternal puncture and the peroxidase reaction. Sternal puncture, performed on Sept. 15, showed: primitive cells

(haemocytoblasts) 42.5%, myeloblasts 35.5%, promyelocytes 15%, myelocytes 0.5%, polymorphs 1.5%, lymphocytes 1.5%, monocytes 0.5%, basophils 1%, plasma cells 0.5%, normoblasts 1.5%. About 60% of the nucleated cells in the bone-marrow films showed the presence of peroxidase-positive granules. On Sept. 16 the white cells numbered 2,500 per c.mm., of which 85% gave positive peroxidase-stained granules. The differential count showed: haemocytoblasts 10%, myeloblasts 32%, promyelocytes 45%, myelocytes 3%, polymorphs 6%, lymphocytes 4%; two normoblasts were seen while counting 100 white cells.

Post-mortem examination on Sept. 17 revealed complete consolidation of the left lung, a few haemorrhages in the left parietal pleura and into the mesenteric fat, spleen slightly enlarged and soft, and bone marrow brownish pink in colour; no other macroscopic abnormalities. The previously described lesions of the skin of the limbs were still present but had become more purple, and those of the legs had lost the vesiculation in the centre.

Histological sections from the skin lesions showed infiltration of the corium with leucocytic cells surrounded by a zone of haemorrhage. The kidney, liver, and spleen contained a very few scattered foci of leucopoiesis. The lung showed the alveoli filled with fibrinous acellular exudate with little inflammatory reaction.

After the report on this case had been submitted for publication, a second case presenting similar haematological features was seen by one of us (B. L. D. V.).

CASE II

A man 41 years old, who had been complaining of lassitude for two to three months and severe headache for the last fortnight, presented the following blood picture when first seen: haemoglobin, 34%; red cells, 1,640,000 per c.mm.; white cells, 10,200 per c.mm. —haemocytoblasts 16%, myeloblasts 42%, myelocytes 2%, polymorphs 14%, lymphocytes 25%, monocytes 1%. Except for marked pallor nothing abnormal could be detected on general examination: spleen and liver were not palpable, and there was no glandular enlargement. Sternal puncture showed a picture very similar to that of the peripheral blood, possibly through the marrow sample being heavily contaminated with peripheral blood. The primitive immature cells were almost identical with those observed in the previous case, and were correctly diagnosed only by means of the peroxidase stain.

White cell counts during the patient's stay in hospital showed variations between 6,800 and 18,600 per c.mm. He was given a large blood transfusion when his red cells reached the level of about 1,000,000 per c.mm., and was sent home, his general condition being much improved. When last seen his white cells had risen to a level of 50,000 per c.mm. with over 80% of very primitive mononuclear forms.

This case also, although not strictly comparable to the first because of the rise in white cells following the transfusion, when first seen in the aleukaemic phase presented a blood picture hardly distinguishable from that of lymphatic leukaemia without the aid of the peroxidase stain.

CONCLUSION

Both these cases are of interest in showing the "hiatus leukaemicus" of Naegeli, consisting of the presence in the peripheral blood of primitive cells and mature forms with few or no intermediate stages. The acuteness of the leukaemic process coupled with a very low white cell count as found in Case I is an uncommon feature. The bone marrow showed definite and marked leukaemic change, but other organs presented little leukaemic infiltration. The low white cell count may have been due either to the minimal leukaemic involvement throughout the body or to the destruction of the immature circulating cells by the spleen, itself not yet involved in the process.

It is worth noting that in both cases the peroxidase stain was essential for the correct classification of the immature cells, which might at first sight have been thought to belong to the lymphatic order.

We are indebted to Dr. J. H. Sheldon, honorary physician, and Dr. S. C. Dyke, pathologist to the Royal Hospital, Wolverhampton, for permission to publish these cases and for much helpful criticism.

S. M. Feinberg and others (*Ann. intern. Med.*, 1943, 18, 311), recording 8 cases of allergic reaction to injected liver extract, suggest that this type of allergy is not uncommon. Their tests indicated that it is neither a species specificity nor an organ specificity involving the usual protein antigen. They believe that the allergic response is to "a special fraction of an organ (liver) not bound with the ordinary protein fractions but associated with the anti-anaemia fraction."

THE DIETARY FACTOR IN REPRODUCTION AND LACTATION

BY

MARION B. RICHARDS, M.A., D.Sc.
(From the Rowett Research Institute, Aberdeen)

Any investigation into the causes of high infant mortality must take account of nutritional factors. Direct proof of the effect of their influence on human beings is hard to obtain, but means of experiments on small animals, in which environment and diet are strictly controlled, it is possible to obtain valuable information regarding the effects of a deficient diet on breed performance, and the possibilities of remedying the deficiency by means of suitable supplements.

A recent breeding experiment on rats carried out at the Institute has given results which seem to be of considerable practical importance at the present time. This was a long-term experiment in which the females, mated at 100 days of age, after being on their experimental diets from weaning, were carried through three successive matings. The object was to determine the effect on reproduction in rats of supplementing a poor human dietary by additions of inorganic calcium, vitamin B₁, given separately and in conjunction; to test the effect of dried yeast as a source of vitamin B, and other factors; and further to test the influence during the breeding period of an increased milk intake along with these supplements.

The basal diet was that employed in the growth tests on rats recently reported (*Journal*, 1943, 1, 161), and represents an average diet of households spending from 3s. to 7s. per week on food. This diet contains milk equivalent to a weekly intake of 3 pints per person, and from the date of mating each group of rats was subdivided, half the animals, both male and female, receiving thereafter a doubled supply of milk.

Table I gives a brief summary of the results of the breeding test, combining the figures for three matings and rejecting animals which failed to produce three litters within six months. It is our practice to reduce all larger litters to 8 on the day after birth—a fact to be remembered in regard to the number of rats reared per litter.

TABLE I.—Showing Breeding Results for Three Consecutive Matings

Group	Dietary Supplements	Litters Born and Litters of 8 Reared	Aver. No. Born Alive per Litter	Aver. No. Born Dead per Litter	Aver. No. Reared per Litter Born	Aver. Weaning Wt. per Rat (Litters of 8) (g.)	Weights of At First Mating (g.)	At Litter (g.)
IIA ..	—	24/4	6.9	0.8	5.4	33.6	185	2
II ..	Milk	30/14	8.8	0.5	6.3	39.1	186	2
IVA ..	Ca	27/13	8.6	0.3	6.9	35.1	202	2
IV ..	Ca + milk	21/14	9.2	0.5	7.4	40.5	196	2
IA ..	Aneurin	27/15	8.0	1.9	6.2	32.2	186	2
I ..	Aneurin + milk	27/14	8.7	0.4	6.8	38.7	185	2

V ..	Ca + yeast + milk	33/23	9.8	0.8	7.0	45.8	209	3

* After rearing litters of 6 to 8.

Effect of Extra Milk

Comparison of the results for the various pair-groups shows at once the beneficial effects of the milk supplement. It is particularly evident in all groups in the weights of the young at weaning and in the weights of the does after lactation. The milk supplement has increased the average weight of each young rat in litters of 8 by approximately 5 to 5½ g., making an increase of 40 to 44 g. for the litter. At the same time the does, in spite of rearing this greater weight of young, have made a greater increase in their own weights. The milk groups show also in general a higher number of young born alive per litter, and a higher proportion of litters of 8 reared. This is especially marked in the basal group, in which the number of young per litter born alive is raised from 6.9 to 8.8.

addition of milk, and the proportion of litters of 8 reared is raised from 1 in 6 to 7 in 15. In the groups receiving calcium and yeast the diet has already been so much improved by these additions that the further addition of milk shows its effect mainly in the weight of the young at weaning, and in the high weight and excellent condition of the does after lactation.

Additions of Calcium and Aneurin

Addition of calcium alone to the basal ration has had a pronounced effect in increasing the number of live young per litter and in raising the proportion of litters of 8 reared, but these increases are no better than those effected by the simple addition of milk to the basal ration, while the increase in the weaning weight of the young due to the calcium supplement is much less than that effected in any of the pair-groups by addition of milk.

Addition of aneurin alone is of doubtful value. There was a considerable improvement, it is true, in the number of live young per litter and in the proportion of litters of 8 reared; but, on the other hand, the percentage of stillborn was high (18.7), the average weaning weight of the young and the weight of the does after lactation were both less than on the basal ration, and the condition of the does was poor. Keeping in view these harmful effects, it would seem that caution must be exercised in the addition of vitamin B₁ to a poor diet. Such improvements as are effected by the aneurin addition can be more simply attained by a milk supplement, and the group receiving both aneurin and milk was no better than that receiving milk alone.

The addition of calcium as well as aneurin reduced the percentage of stillborn (cf. IA and IIIA), and increased both the weaning weights of the young and the weights of the does after lactation. The gradation seen in the weaning weights in Groups IIA, IVA, and IIIA—33.6, 35.1, and 36.5—is repeated in the corresponding groups with extra milk—39.1, 40.5, and 41.9.

Addition of Calcium and Yeast

Direct comparison of Group VA with Group IIA brings out very clearly the great improvement in the diet brought about by the addition of calcium and yeast. The number of live young per litter is increased from 6.9 to 9.8, the proportion of litters of 8 reared is raised from 1/6 to 5/6, while the average weaning weight per rat in litters of 8 is 7.3 g. more, representing an increase of over 58 g. for the whole litter. The addition of milk to the calcium and yeast group brings this increase per rat up to 12.2 g., making the weaning weight 45.8, which is approximately the average weight of a stock rat at weaning.

The groups receiving calcium and yeast were outstanding throughout the experiment. In their appearance and general performance, especially Group V, they were quite comparable with stock rats.

One of the most noteworthy points in the experiment was the striking difference in the condition of the does after lactation. In Groups IA and IIA some of the does were in such a limp and exhausted condition after rearing their litters that they had to be given a few days' rest before remating—a procedure which was unnecessary in the corresponding groups receiving the extra supply of milk. The differences in the condition of the does may be gauged by the differences in their average weights after rearing litters of 6 to 8 in the third mating. Thus in Group V the average weight of such does is 302 g., as compared with 228 g. and 214 g. in Groups IIA and IA.

The results indicate that the yeast supplement has made good certain deficiencies in the diet not already supplied by the calcium, milk, and aneurin, and that the simultaneous addition of calcium, yeast, and milk has converted a poor diet into one on which the breeding performance is on a par with that of stock rats.

Deaths during the Suckling Period

During these breeding tests it was noted that in a number of cases one or more rats in a litter died, without any apparent cause, within a few days of weaning age. These deaths occurred almost entirely in the groups receiving the unsupplemented basal ration, and in this respect the milk subgroup was no better than that without the extra milk. In Table II are given the number of deaths that occurred among the sucklings at

different periods, ignoring the first 24 hours after birth, when accidental deaths are apt to occur, especially with large litters.

TABLE II.—Deaths during Suckling Periods

Groups	Supplements	No. of Does	No. of Young Born Alive	In Reduced Litters (after 24 Hrs.)	Deaths during Suckling			
					2-6 Days	7-11 Days	12-23 Days	Total
II and IIA	—	18	431	356	20	3	16	39
IV and IVA	Ca	16	425	354	8	3	0	11
I and IJA	Aneurin	18	451	361	7	0	3	10
III and IIIA	Ca + aneurin	20	529	416	9	1	0	10
V and VA	Ca + yeast	21	615	458	4	0	0	4

Although it is not unusual to have deaths occurring in the first few days of the suckling period, it is to be noted that even at this stage they are appreciably fewer in the groups receiving supplements. Deaths in the later stages do not normally occur with healthy animals, and the high number occurring on the basal ration in the latter half of the suckling period is undoubtedly of significance. It will be seen that in the groups receiving Ca alone, Ca with aneurin, or Ca with yeast there was no death at all during this period. Further, in the yeast groups the total number of deaths is very small relatively to the large number of young reared, and there was no death after the first few days.

Conclusion

These records show clearly the importance of the diet in matters concerning breeding performance in animals in controlled environment, and indicate the large part it may possibly play in the problem of infant mortality in human beings. While it is disquieting to reflect that the basal diet used in these experiments is not that of the poorest classes in the community but is representative of the diet of large masses of our population, the fact that it may be radically improved, for experiments on animals, by the addition of such simple supplements as inorganic calcium, milk, and dried yeast gives ground for the hope that it may be similarly improved for purposes of human nutrition. Recent dietary surveys have indeed shown that the diet of pregnant and nursing women of this socio-economic group has been improved during the war by means of the milk priority scheme and by the introduction of national wheatmeal bread. Moreover, despite adverse housing conditions, restricted medical service, and an increase in the number of married women going out to work, the infant mortality rate in Scotland for 1942 fell to 69 per 1,000 live births, a figure equal to that for 1939, which was the lowest recorded up to that date; while in England and Wales the rate for 1942 was the lowest ever recorded. Our experimental results show the possibility of a connexion between these two sets of facts, and indicate how further improvements in the diet may be effected. At the same time they provide useful pointers for the post-war feeding of the starved populations in Europe.

METALLIC INTERNAL FIXATION OF FRACTURES IN AIR-CREW CASES

BY

N. VERE-HODGE, M.B., B.Chir., F.R.C.S.

Squadron Leader, R.A.F.V.R.

Internal fixation of fractures with metal plates and screws has been coming more and more into use for several years, with the result that an ever-increasing number of men are working with metal plates and screws in their limbs. Until recently the metals available showed a slight reaction within the body tissues, though not necessarily enough to interfere with their usefulness. Within the last ten years an alloy—vitallium—has been produced which is inactive in body tissues.

The discovery of vitallium has given further impetus to the use of metal internal splintage of fractures. During the present war a very large number of fractures have occurred

in men of the younger age groups. It is vitally important to the war effort that they should be returned to duty as soon as possible and with the minimum functional disability. It is with this end in view that certain types of fractures are being treated with internal fixation by vitallium plates and screws. In the R.A.F. many air-crew fracture cases have been treated with vitallium plates and screws. After the stage of full rehabilitation has been reached the airman returns to his unit to resume flying. In consequence numerous air-crew members are now regularly flying with large metallic plates and screws retained in their limbs.

The purpose of the present inquiry is to make certain that these men are not a menace to the other members of their air-crew by upsetting the compass readings on account of their "personal" metal.

The Investigation

Vitallium is now most commonly used, when available, owing to its superior properties. However, when not available stainless steel is found to be the next best material. For the purpose of this investigation two sets of these materials were tested: (i) a 14-hole stainless-steel plate 7 in. long and 5 stainless screws $1\frac{1}{2}$ in. long, such as might be used for a fractured femur or a fractured tibia; (ii) a vitallium plate $5\frac{1}{2}$ in. long and 4 vitallium screws $1\frac{1}{2}$ in. long, such as might also be used for a fractured femur or tibia.

The two sets of metal were tested for magnetism in the following way: First, (i) and (ii) were tested for their effect on an aircraft compass: no effect was discernible. Secondly, attempts were made to magnetize each component of (i) and (ii) separately, stroking with a permanent magnet. (i) and (ii)

demagnetized by ordinary methods such as mechanical vibration or striking with a hammer. Although two of the stainless steel screws retained their magnetism for three days to the same extent as the plate, they are likely to lose it in a short time, as the other three screws did. The vitallium plate and screws could not be magnetized by these powerful methods.

To complete these tests several airmen with stainless-steel or vitallium plates and screws in their upper or lower extremities have been tested against an aircraft compass. In all cases there has been no deviation of the compass needle.

Conclusions

These tests show that vitallium plates and screws are entirely safe as regards magnetism when used for treatment of fractures in men who fly aircraft.

Stainless-steel plates and screws are magnetized only with the greatest difficulty, and then tend to lose their magnetism gradually. When handled by the usual surgical method it is extremely unlikely that they would affect an aircraft compass.

As a result of the tests on the magnetic properties of these metals, surgeons should feel quite justified in leaving stainless vitallium or stainless steel in the limbs of their fracture cases and there is no indication for removal of either of these metals before returning the men to full flying duties.

I wish to thank Group Captain J. M. H. Whitworth, D.S. D.F.C., for his help in carrying out the tests which form the basis of this report; also the Director-General of Medical Services R.A.F., for permission to publish this report.

Medical Memoranda

Incidence of Syphilis among Juvenile Defectives

The following is a record of the blood Wassermann reaction of juvenile patients admitted to the Fountain Hospital from the years 1938 to 1942 inclusive. All were mental defectives, most of the lowest grade.

Year	Admissions	Positive W.R.	Average Age yrs. mth.
1938	80	—	4 3
1939	175	2	7 7
1940	98	—	4 6
1941	45	2	4 9
1942	114	—	4 9
Total	512	4	5 6

These results are of interest because of the low incidence (0.78%) of syphilis that they reveal, and they provide evidence on the question of the general incidence of syphilis. Many of these patients have parents with some degree of amentia, and it might be expected that a general increase in syphilis would particularly affect these members of the population and would be reflected in an increase of congenital syphilis in their children. However, the figures indicate that congenital syphilis is not now the important factor in the aetiology of amentia that it formerly was, for it seems that among older mental defectives a positive blood W.R. is much more common than in this group.

Syphilis would therefore appear to be decreasing among parents of mental defectives, although a possible alternative explanation of the results is that an increasing proportion of mothers may be seeking ante-natal examination and receiving successful treatment if syphilitic.

It is interesting to note that extremely inconsistent results have been obtained by different observers in this work. Penrose (1933) gives a table of findings of positive Wassermann groups of defectives varying from 1.5 to 55%, the highest percentages being in the largest groups. Other authorities regard 10% as a fair average.

J. LLOYD, M.D., M.R.C.P.

REFERENCE

Penrose, L. S. (1933). *Mental Defect*, p. 38, London.

Photograph of vitallium and stainless-steel plates and screws.

were then tested for their effect on an aircraft compass, and again no deviation was discernible. Thirdly, the components of (i) and (ii) were treated by a high-power remagnetizing plant. After this treatment (i) and (ii) were retested for their effect on an aircraft compass. The position adopted in relation to the compass needle was with the nearest end of the component 1 in. distant from and level with the centre of the compass needle, with the ends of the component under test at right angles to the axis of the compass needle. Three days were allowed for natural demagnetization. At the end of three days the results were:

	Compass Deviation*	
(a) Stainless steel plate	+2°	-2°
(b) Stainless steel screws, No. 1	nil	nil
" " " No. 2	+2°	-2°
" " " No. 3	nil	nil
" " " No. 4	nil	nil
" " " No. 5	+2°	-2°
(c) Vitallium plate	nil	nil
(d) Vitallium screws	nil	nil

* Second figure obtained with polarity reversed.

From these tests it is found that the stainless-steel plate, though difficult to magnetize, after being magnetized has an appreciable effect upon a compass, and it cannot be

Reviews

THE INNER EAR

The Inner Ear, including Otoneurology, Otosurgery, and Problems in Modern Warfare. By Joseph Fischer, M.D., and Louis E. Wolfson, M.D. (Pp. 421; illustrated. 55.75.) New York: Grune and Stratton Inc.

The authors of this book have tried to draw a somewhat artificial distinction between the different parts of the ear—a distinction which is no doubt clear enough in the mind of the anatomist, but less so in the mind of the physiologist and the pathologist, and not recognized at all by Nature herself. The authors consider that the middle ear is sufficiently described in the ordinary textbooks of otology, but not so the inner ear, and they have attempted to supply the deficiency. The book, however, has resulted in a series of essays, each attributed to one or other of the authors, upon particular topics, and necessarily overlaps both by some repetition and by extension into subjects which are interesting and important but not strictly relevant. On the other hand, either some matters are omitted or their discussion is suddenly cut short, on the ground that the inner ear is not directly concerned. Thus there is a valuable chapter on chemotherapy, but this relates far more to general considerations, and to the middle ear in particular, than to the inner ear. In discussing intracranial complications the situation becomes still more illogical, for abscesses of the cerebrum, being usually secondary to disease of the middle ear, are dismissed briefly, while abscesses of the cerebellum, being more often a complication of infection in the labyrinth, receive much fuller treatment.

In view of the handicap which the authors imposed upon themselves, but have not strictly respected, they have produced a useful but from its very nature an ephemeral piece of literature, which would have been more readable had it been written better. It may perhaps be thought pedantic to insist too strongly upon this aspect of a medical book; but, apart from the pleasure and ease it gives to the reader, good writing demands clarity both of thought and of expression. The lack of these is only too evident and too frequent, the chapter on meningitis being a conspicuous example, and that on Ménière's syndrome another. The authors, however, have made a gallant attempt at the exposition of an extraordinarily difficult subject and display a profound knowledge of the pathological changes that occur in the inner ear. The publishers have given generous support, but the numerous illustrations of morbid anatomy, chosen from the authors' own collection, mostly convey very little to the reader, whereas stereoscopic illustrations would have provided that additional help to the eyes necessary for the appreciation of labyrinthine pathology. In the matter of references, which are a cardinal part of such a book, we find much to criticize, for numerous authors are mentioned in the text without acknowledgment in the references, and, on the other hand, authors appear in the references without mention in the text. Although the defects of the book are evident enough, it does reveal a comprehensive effort to describe from many points of view a subject in which great advances have been made in recent years, in which many problems are still unsolved, and many observations still appear contradictory. The authors at least have not been overwhelmed by the difficulty of their task and the many uncertainties that confronted them.

HUMAN INHERITANCE

The Treasury of Human Inheritance. Edited by R. A. Fisher, F.R.S. Volume IV. Nervous Diseases and Muscular Dystrophies. Part IV: On Pseudohypertrophic and Allied Types of Progressive Muscular Dystrophy. By Julia Bell, M.A., F.R.C.P., With Pedigree Plates XXXIII to XLIV: Figs. 567 to 539. (Pp. 58. 12s. 6d.) Cambridge: The University Press, 1943.

In previous reviews and annotations we have found much to praise in this beautifully produced series of monographs. The present example does not fall short of its predecessors either in the manner in which an extensive literature is summarized and presented or in the interest of Miss Bell's brief introductory remarks. She shows that it is possible to group cases of progressive muscular dystrophy into three fairly distinct clinical types. This differentiation, though imperfect, does show a marked correspondence with the mode of transmission, which,

as is so often the case in the human subject, may be different in different families. Recessive cases are commonest, though the more striking sex-linked pedigrees have been more frequently recorded. Dominant cases are very rare, though direct transmission, when it does occur, may lead to very large numbers of affected persons in a single family group, and in a civilized community the pedigree will almost certainly appear in the medical literature. Thus three genes at least may produce the condition, but the number is greater than this, for the correlations between members of a single family group as regards both age at onset and age at death are very high. This is an indication that even within the limits of one mode of transmission different genes are at work in different families.

Once again the value of the monograph is enhanced by the inclusion of a series of consecutive cases, 113 in number, seen at the National Hospital, Queen Square. The pedigrees are, as always, clearly presented, there is a full bibliography with an index, and extensive summaries are given of the original clinical notes. This publication is a welcome addition to the *Treasury* which Prof. Karl Pearson inaugurated and which has been continued on the same generous scale by Prof. R. A. Fisher, his successor in the editorship.

"ROSE AND CARLESS"

Rose and Carless Manual of Surgery for Students and Practitioners. By Cecil P. G. Wakeley, F.R.C.S., and John B. Hunter, M.Chir., F.R.C.S. Volumes 1 and 2. Seventeenth edition. (Pp. 1,766; illustrated. 35s.) London: Baillière, Tindall and Cox, 1943.

A book that reaches its seventeenth edition in forty-five years must have many virtues to account for its prolonged success. This is certainly true of *Rose and Carless's Manual of Surgery*, so well known to all the older generation of doctors. When it first appeared in 1898, and for many years afterwards, its popularity was unchallenged; within recent years, however, some formidable rivals have come to dispute its supremacy. There can be no doubt that the modern student is inclined to look with less favour upon "Rose and Carless" than did his father. The reviewer was reared on this surgical vademecum and has in consequence always felt a great and friendly interest in its fortunes. For that reason the present edition has been examined critically to see if any change in its character could be detected to account for the loss of popularity among students and teachers, for at its inception this book was a considerable contribution to the education and teaching of the aspirant to surgery. It will be seen, therefore, that any criticism is inspired by friendliness and proffered in a spirit of helpfulness.

The most significant change to be noted is a tendency to loss of balance, uncommon conditions being sometimes given two or three pages of description and fully illustrated, when really important, but perhaps somewhat less interesting, diseases are inadequately dealt with. In a short review it is not possible to give more than two examples of this. Under the heading "Varicose Veins" surgical treatment is dismissed by the statement, "Excision of varicose veins, although practised extensively in the past, has been entirely replaced by injection treatment"; no mention is made of the Trendelenburg operation, which, combined with injection, is now probably one of the most frequently performed and successful methods of dealing with many cases. Yet we have an account and a good illustration of intramedullary tractotomy in the treatment of trigeminal neuralgia, while pineal tumours occupy some five pages of text and illustrations. Again, there is no mention of excision as a method of treatment of fractured patella, though this has now been used long enough to prove its value in suitable cases, but Dandy's method of treating hydrocephalus by cauterization of the choroidal plexus through a ventriculoscope is thought worthy of both description and illustration. In extenuation the authors explain in the preface that the revision for this edition has not been as thorough as they would have liked owing to wartime conditions.

The illustrations are good: it is pleasing to see that some of the originals have stood the test of time and still appear. The general production also is good, and the continued use of surfaced paper has enabled the illustrations, both coloured and plain, including the radiographs, to reproduce well. Despite the criticisms, therefore, we still think that "Rose and Carless" is a very fine representative of the English student's textbook of surgery; he is unlikely to go far wrong in following its precepts.

Notes on Books

Minor Surgery, the latest of the handbook series to be published by the Practitioner (Byre and Spottiswoode, 16s.), is launched with an introduction from Sir Alfred Webb-Johnson, P.R.C.S., whose quotation from the Prayer Book on the honourable estate of matrimony applies equally well to the high standard which should be expected in performing even the so-called minor procedures of surgery. The book is composed of revised articles which originally appeared month by month in our contemporary. Fractures are not dealt with, as these comprise a separate and recently published book which has already been noticed in this column. As samples of the eighteen chapters which comprise the present book we may mention: varicose veins, ulcers, and phlebitis, written by Reginald Payne; gynaecology, by Douglas Macleod; wounds, by C. P. G.

Wakeley; anaesthesia and analgesia, by C. Langton Hewer; the eye, by J. S. Arkle; the ear, by C. P. Wilson; sprains, by G. J. Girdlestone; and minor surgery of the genito-urinary system, by Clifford Morson. Bursae and ganglia make an interesting article by H. Jackson Burrows, and skin infections by Prof. Rendle Short should be most helpful to the general practitioner, whom most the authors apparently have in mind and who is likely to benefit most from the book. Wartime economy has required the illustrations to be grouped together into a series of plates, but these are well produced, and the whole forms a very convenient little book in which practitioners will find well-written and brief accounts of modern methods of dealing with those apparently trivial, but really by no means trivial, maladies which may cause him to enter the realms of surgery, even if it is not to proceed very therein.

Preparations and Appliances

RESUSCITATION AND OXYGEN-THERAPY APPARATUS FOR INFANTS

Dr. RODERICK H. O'HANLON, late auxiliary medical officer, Rotunda Hospital, writes:

The accompanying photograph illustrates the combined resuscitation and oxygen-therapy apparatus for infants now in service at the Rotunda Hospital, Dublin. Experience at the Rotunda has demonstrated the great value of oxygen in the treatment of all cases of critical asphyxia in the newly born, but the apparatus employed heretofore was unable to cope with the many practical problems which arise in the administration of oxygen to the infant (as distinguished from the adult), and particularly in the treatment of the premature infant. During my term of office as auxiliary medical officer at the Rotunda and under the direction of the Master, Dr. Ninian Falkiner, I made a study of these problems and designed the apparatus with a view to overcoming them.

The resuscitation unit is an adaptation of the method devised originally by Dame Louise Mellroy, and employs a predetermined mixture of oxygen and carbon dioxide in association with a mechanical frequency indicator to assist the operator in regulating application to conform with the normal breathing rate. The cylinder containing the mixture is fitted with an automatic reducing valve, and therefrom a baffled flexible pipe line leads to a pistol-grip trigger-valve and to a baby's anaesthetic mask. After a thorough clearance of the respiratory passages by means of a mucus catheter the infant is placed in the cradle with suitable coverings to promote warmth. The mask is then applied and removed at intervals signified by the frequency indicator. Pressure on the trigger-valve permits a volume of gas to escape just sufficient to produce a very slight positive pressure on the alveoli. Release of the trigger cuts off the flow of gases, and the flexibility of this arrangement, together with an intelligent use of the frequency device, makes it easy for an unpractised operator to develop a sound technique. While resuscitation is in progress the oxygen chamber may be warmed up and, when breathing has been initiated and established, the cradle containing the infant may be slid directly into the gas chamber without delay. The baby is then subjected to oxygen therapy under proper conditions of humidity and temperature for as long a period as may be desired.

The oxygen-therapy unit, which is an open circuit, comprises two oxygen cylinders fitted with reducing valves and cross-coupled in such a way that when one cylinder becomes empty the other cuts in automatically and starts to deliver gas. The empty cylinder may then be removed and a full one substituted in a few minutes,

so that, if necessary, operation of the apparatus may be continued over a long period. The gas flowing from the cylinder goes to a standard adjustable flowmeter and thence to a standard humidifier to the injector, or, if desired in very hot weather, via a specially insulated ice-box to the injector. The gas enters the chamber downwards, so that the cold oxygen admitted lies on the bottom and warm air is displaced upwards and passes out—thus keeping loss of oxygen at a minimum during flooding. The temperature and humidity of the gas delivered to the chamber may be varied within limits. The chamber is flooded with known quantities of oxygen, depending on what initial concentration of oxygen is required. Thereafter it is maintained or varied by regulation of the injector. The gas chamber is constructed of hard wood with plate-glass top, a metal floor, and a gastight door. When the door is opened downwards the wire cradle containing the infant

bedding may be slid in or out of the gas chamber on rollers run on slides. Wet- and dry-bulb thermometers are fitted in a way as to be readable from outside the chamber. Immediately beneath the metal of the gas chamber explosion-proof electric heaters are fitted with a metal reflector backed with asbestos and hard wood. The heaters are thermally controlled by thermostats, one of which is variable between 67° F. and 77° F. and the other is a stand-by safety device to prevent the temperature of the chamber from rising above 80° F. The thermostats may be "locked" for higher temperatures if desired in an emergency and the treatment of the mature infant the

temperature inside the chamber may be raised to the desired level very quickly, since the heaters are wired in such a way as to cut both or one or half of one to be put into operation by a convenient switch. Once the desired temperature has been obtained the power is cut down, and thereafter the temperature is maintained by the thermostat. Provision has been made for the important detail of intervenous drips to the infant during treatment in the gas chamber. The entire gas chamber may be tilted from the horizontal by turning a handle. Since the cradle is reversible the body of the infant may be inclined in either direction.

I have to acknowledge the kind co-operation of Mr. L. of the Electricity Supply Board in regard to the heating arrangements, to thank Mr. Aitken and Mr. Swan of Medical Gases, for the run of their laboratory for experiments, and to express gratitude to Mr. Peter McCarthy of Messrs. O'Dea, Ltd., who undertook and completed the construction of the apparatus during the drastic limitation of all supplies resulting from the war.

THE PUBLIC CORPORATION

BY

D. HARCOURT KITCHIN

Barrister-at-Law

[Concluded from p. 400]

The Assistance Board

The Assistance Board was set up under the Unemployment Assistance Act, 1934, to supplement the unemployment insurance scheme by assisting those who had exhausted their benefits whose benefits were not enough, and so making it unnecessary for them to apply for public assistance. In 1940 the Board was renamed the "Assistance Board" and given the extra work of granting supplementary pensions to old age pensioners and elderly widows. Soon afterwards, by emergency legislation—the Prevention and Relief of Distress Rules—it was authorized to relieve any distress directly resulting from the war. As agent for the Ministry of Pensions it pays injury allowances to civilians injured by enemy action, and investigates applications made to the War Services Grants Committee. On behalf of the Board of Trade it makes grants to replace clothing and essential furniture destroyed in air raids.

The Board is composed of five members with long experience of social work, appointed by the Crown. It was originally responsible only to the Minister of Labour, but now no longer than eight Ministers may speak for it in Parliament on the various aspects of its work. Its grants are paid through the labour exchanges or the post office. Dissatisfied applicants may appeal to a tribunal composed of an independent chairman, a representative of the Board (not in practice a member of it), and a representative of labour. The Board receives indispensable help from local advisory committees and from other statutory and voluntary social services. Its local administration is done by its paid staff, who are directly responsible to the central office.

The Assistance Board is perhaps more significant to the question of a medical services corporation than is any of the other bodies that have been described. It has no commercial functions but purely philanthropic ones. It has a nation-wide organization, and is financed entirely from the Treasury. It renders services that concern the intimate personal lives of very many subjects. Unfortunately, this particular Board, which contains a far closer precedent for the projected corporation than do any of the others, has aroused in its time far greater public hostility than have all the rest put together. It was created as an experimental means of dealing with a very urgent social problem—a large and growing number of persons unemployed through no fault of their own whose needs hampered the existing insurance scheme. It was the centre of very strong and widespread political emotion. Immediately it started its work it aroused a storm of fury among the unemployed and their political champions by paying many allowances smaller than the "transitional payments" which the applicants had previously been receiving. The Government could certainly have been defeated if it had not at once suspended the operation of the Board by the famous "Standstill," provisionally a decision of the Board to pay allowances at transitional rates until a new set of regulations could be adopted.

The "Standstill" lasted for two years, and since its ending with the introduction of a more generous scale of allowances and better regulations the Board has gradually won for itself general public confidence and approval. The crisis at its birth was not due to its form or constitution, but to the insufficiency of the funds which the Government and Treasury were willing to allot to it, to the inevitable inexperience of its staff in the use of discretion, and to the clumsiness of the Government in trying to shelter behind it. The Board has never had anything like the independence of the commercial public corporations, but none the less has learnt to do its work so well that it has been given heavy and important additional duties—not a bad test of the merits of an organization or an individual. The projected medical corporation might be similarly hampered by inadequacy of funds, and its work might be similarly bound up with politics. Its advocates would have to be prepared for close co-operation with the Minister and detailed scrutiny in Parliament at least for some years to come.

Agriculture in Wartime

It is profoundly interesting that one of the most striking examples of an independent body administering a public service should have arisen out of the needs of the country at war. At a time when the whole tendency of national administration is towards bureaucracy, the Minister of Agriculture and Fisheries, using his almost dictatorial powers, has created one of the freest and most democratic of all our public institutions. The County War Agricultural Executive Committees have succeeded in producing from the fields of the country an amount of food which no one before the war thought possible, and in immensely lightening our shipping problems.

The Defence Regulations made in Council under the Emergency Powers Act give the Minister of Agriculture (along with other Ministers) a very free hand in matters within his province. Under those powers Sir Reginald Dorman-Smith, himself a farmer, appointed in each administrative county a War Executive Committee, taking as a nucleus the members and staff of the existing agricultural committee of the county council and adding persons whose position in the agriculture of the county would make them valuable members. The executive committee works through a varying number of district committees appointed by itself from the principal farmers and landowners of the districts. (These are not the rural districts, but have been marked out *ad hoc*.) The district committees' functions are advisory only; the county executive committee has wide powers delegated to it by the Minister under various statutory Orders, but in general it is bound to obtain the approval of the Minister for very drastic actions, such as dispossession. Through its large and expert staff it is informed of every detail of the county's agriculture practically from day to day; it decides what shall be done with every acre of land and how many animals each farmer shall keep. It controls the issue of feeding stuffs and seed, subsidizes ploughing, sends machines and men to work where they are needed, and cultivates with its own labour pool large tracts of reclaimed land. It regulates its own procedure, chiefly on county council lines. Its legal status is obscure, for it was created by an executive, not a legislative, act of the Minister, and is probably not in law a corporation at all. It has no common seal, but acquires land and property by requisition as an agent of the Crown under the Minister's emergency powers. A person wishing to sue it issues his writ against the chairman and the executive officer. Nevertheless, it is so like a corporation in its structure and behaviour that it may fairly be treated as one.

Each executive committee is in constant touch with the Ministry through its officials, and is guided in policy, and no doubt also in many details of execution, by confidential circulars. It constantly instructs and receives reports from its district committees. It appoints subcommittees to deal with different departments of its work, and their members spend much time on the land in contact with the farmers and labourers. Its patience, gentleness, and practical wisdom give the farmers that security and confidence which men must have if they are to create and produce. These wholly admirable qualities have flowered in a situation full of urgent compulsive necessity. Whether they could be evoked after the war, when they will appear to be merely desirable and not indispensable, is part of the fundamental question of our times.

Space does not permit more than the bare mention of the other little-known but useful public corporations like the Land Drainage Boards, the Coal Commission, the legal owner of the coal mines (appointed by the Board of Trade), the Herring Industry Board, the various agricultural marketing boards, and the War Damage Commission (appointed by the Treasury).

A Health Services Board

These are the chief examples of the public corporations at present working in this country. Obviously this form of administrative body can be successfully applied to a great variety of public services: to any service, in fact, which is vital to the public good and which implies a monopoly. None of the services rendered by the existing corporations, however, has much in common with the projected national medical service. Many new problems would be encountered in an attempt to organize a public corporation which should provide the comprehensive medical benefits of a scheme on the lines

of Sir William Beveridge's report, and in many ways such a body would differ from any of its predecessors.

The committee which met to design it would have first to settle its size and composition. None of the conditions which Gordon lays down as appropriate for a representative, as opposed to an appointed, board is here fulfilled. Geographically the work would extend over the whole country, the interests which could justly claim representation are innumerable, and the many million "consumers" of the services would be neither organized nor organizable. The board would have, then, to be appointed, but the drafting committee might well ask themselves whether the appointments should not follow a broad plan of representation—e.g., that a stated number of members must be medical, or that one or more members must be lawyers, or actuaries, or labour leaders, or women. The next question is who is to appoint these members. The committee would have to consider whether they could trust a Minister, or whether they would put responsibility for selection on the Crown—i.e., the Prime Minister after consultation with the members of the Government concerned—or on some special appointing body of eminent persons like that which fills vacancies in the L.P.T.B. They would then have to lay down the number of the board, remembering that it must be large enough for the necessary committee work and not so large as to cease to be a team.

Next, would the chairman be a whole-time salaried executive—a managing director as in the C.E.B.—or would he and the board direct policy through the executive officer? What would be the tenure of office and the salaries of the board? Should members of Parliament be excluded, and would it be necessary to forbid the retention by members of the board of any financial interest in the medical services? Who would have the right to remove a member from office for misconduct, incapacity, or absence? Would a retiring member be eligible for reappointment?

Then, what would be the manner of the board's responsibility to Parliament? In discussions on the formation of the board with representatives of the Government, it might perhaps be urged that the board should be entitled by statute to an actuarially just proportion of the contributions to the general insurance fund, and that this proportion should not be subject in lean times to the arbitrary raids by the Treasury which have so handicapped the B.B.C., or to the arbitrary reductions in allocated revenue which have so handicapped the Forestry Commission. It would thus not be dependent upon an arbitrary allocation, or subject to continuing control by either the Treasury or any other Department over the way it used its revenue, still less over its day-to-day administration. Granted that the board disposed of adequate financial, economic, and actuarial skill, experience, and advice, it should be left a free hand to make the best possible use of its resources. To tie its hands by detailed rules and restrictions would cripple its initiative, creative force, and effectiveness. It must not be made a subdepartment. So long as it showed each year that it had made reasonable use of the funds entrusted to it, the Treasury and the Ministry should leave it alone.

Who would be responsible to Parliament for the general policy of the board and speak there in its name? The Forestry Commission is represented by one of its number who is a member of Parliament and who interprets to it the will of the House. This arrangement, as the Commissioners' report says, "is well enough"; but the work of the Forestry Commission does not touch the individual intimate personal lives of millions of people, and cannot arouse the perpetual interest and controversy which would certainly surround the work of the projected board. The drafting committee might think it probable that neither Parliament nor public opinion would be satisfied with such a tenuous link as a parliamentary commissioner between the House and a board spending millions of pounds and caring in countless ways for the health of millions of citizens, but would demand that this vital service be supervised by a Minister of State. The Minister would presumably be the Minister of Health. Even if the Government saw fit to place, as has been suggested, the whole of the country's health services under the projected board, the Minister of Health would probably continue to exist in order to fulfil the many functions outside the health services proper which he now discharges. The suggestion has been made that the board should

be placed under the supervision of the Privy Council, but the drafting committee would have to take account of a number of serious objections to this proposal. The Minister of Health certainly appears at first sight to be the most suitable constitutional guardian and spokesman of the new board.

The drafting committee would also have to plan the ramifications of the board's structure: to decide whether the board's activities should be directed from London or executed by its officers throughout the country, or whether regional satellite boards should be created, dependent on a central board for policy but autonomous in its execution. The committee might also make provision for the setting up of advisory committees. The board's powers to contract with persons and bodies for services and for the sale or lease of property would have to be precisely laid down, and arbitral and appellate mechanism devised. Its financial powers and duties would have to be set out in detail. The right of employees to superannuation might also demand provision. When the drafting committee had settled these questions it produced a sound scheme and a draft Bill, the harder work of persuading the Government and Parliament to adopt it would begin.

Nova et Vetera

BRITISH AND AMERICAN MEDICINE YESTERDAY

A writer in the *Edinburgh Review* in 1820 concluded an article on American medical statistics with a series of rhetorical questions: "In the four quarters of the globe, who reads an American book? or goes to an American play? or looks at an American picture or statue? What does the world owe to American Physicians or Surgeons?" These questions reflected the European attitude towards the United States merely during the beginning of the last century but well into this. To these slights Nathaniel Chapman answered in a characteristically American manner. In that same year he brought out a journal which was the precursor of the present *American Journal of the Medical Sciences*, and the title-page of the journal carried as its motto the quotation from the *Edinburgh Review*. No love was lost between the two English-speaking branches of medicine. Chapman in 1824 pointed out the "impertinence and presumption" of English critics, who claimed that a particular technique for the treatment of strictures of the urethra, said to have been first described by an English surgeon, was in fact described by an American the year before. Contemporary English medical literature provided Chapman with full opportunities for questioning English gentility. Thomas Wakley, founder of the *Lancet*, used choice descriptions such as "bats," "owls," "cocksparrows," and "ninny hammers" for prominent British practitioners, and these appellations were matter of fact to American critics were unlikely to ignore. Minor events, such as the exploits of John St. John Long, brilliant charlatan who imposed on pre-Victorian society, were further grist to the American mill. Streaks of sanity did however, occasionally break through on both sides. Wakley in 1831, could praise the *American Journal of the Medical Sciences* as being "in most respects superior to the great majority of European works of the same description"; an American editor in 1846 could make the common-sense observation, "Where is the American who would not be pleased, and gratified, to see his works republished, with or without annotations, in Great Britain?" None the less, the dreary game of fault-finding went on throughout the century, charges of ignorance and incompetence being apparently one of the main items of trade between the two countries. One of the earliest signs that this unedifying utility was subsiding was a comment in the *British Medical Journal* in 1883. "Medical journalism in America shows great activity," it says, and speaks approvingly of a series of American publications. In retrospect the Anglo-American hostility, as reflected in medical literature, has little to justify itself, and the conflict has ceased to have a meaning to the present generation, for the conditions from which it arose have long ago disappeared.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 2 1943

CORPORATION OR DEPARTMENT?

he "corporate body" advocated last week by the Representative Body as the most promising means of building and administering a national medical service is, strangely enough, no novelty. Nearly a hundred years ago, in 1848, this country had a General Board of Health. That board was not responsible to any Minister. The principle of Ministerial responsibility, now recognized as vital if the people are to retain any control over a highly specialized executive, was then fighting for existence against the principle of "expert" or "judicial" administration. The Board of Health, the Poor Law Commission, and other similar independent bodies were experiments in applying the second of these two theories to the problems of a new age. The Poor Law Commission perished in 1847 because, as Walter Bagehot¹ said, the House of Commons would not let it alone. In 1858 the Board of Health followed it, having lost its independence four years earlier. Those were the years of the *Communes* and Garibaldi: peoples all over Europe were revolting against autocratic rule, and modern democracy was being painfully born. Ministerial responsibility, however, has the defects of its qualities. Because a Minister knows that the most trivial act of any of his subordinates may lead to a question or derogatory speech in Parliament, he and his Department tend to aim at forestalling complaint rather than at achieving progress. Decisions are referred through an unwieldy hierarchical pyramid to the man at the top instead of being taken by the officer face to face with the problem. Overmuch labour is devoted to records and statistics. These and other drawbacks—not insuperable, nor peculiar to government by responsible Ministers—partly explain the survival of the public board as an administrative service, and its recent access of scope and importance. As a contributor has shown in these columns during the past fortnight, the variety of public services run by more or less autonomous boards is very large. It includes port facilities, the supply of water to London and electricity to the whole country, broadcasting, forestry, London passenger transport, wartime agriculture, produce marketing, land drainage, the relief of distress, and the control of the medical, dental, and nursing professions.

Superficially the autonomous board might seem to owe its success to its freedom from Parliamentary and Ministerial control over its day-to-day functions. Yet a closer examination shows this appearance to be a fallacy. The reverse is the fact: a board's immunity from Parliamentary criticism and Ministerial interference is earned by its success in satisfying the public. The Port of London Authority, the Metropolitan Water Board, and the London Passenger Transport Board have never excited much criticism in Parliament, just because their functions and their discharge of these have never aroused acute political controversy. When the British Broadcasting Corporation's charter was renewed seven years ago Parliament freely criticized its doings in detail. The Unemployment Assistance Board was set up in 1934 by a Government which was misguided enough to think it could escape the odium

of reducing dole payments by giving the task to a theoretically independent body. This Board instantly became the centre of such a furious political storm that the Government escaped extinction only by suspending for two years its discretion to pay allowances lower than the transitional rate of benefit. The whole Parliamentary history of public boards from the earliest times shows that if Parliament really wants to scrutinize and criticize them Parliament will succeed in doing so just as if they were Government Departments run by a Minister. No statutory provision will avail to insulate them from substantial Parliamentary pressure, or from the consequent Ministerial pressure, without injuring the Government of the day. The utmost their autonomous status does is to enable a Minister to resist questions and criticisms which touch administrative detail and are not backed by any considerable public feeling. This protection from "sniping" is admittedly important to the quasi-commercial boards. Nevertheless, a board administering a comprehensive national health service under the Beveridge plan—a service which would affect nearly every citizen in the most intimate details of his life—would inevitably attract continuous and intense interest, criticism, controversy, and without doubt also hostility. Because most of its beneficiaries would belong to the poorer classes and many to trade unions, much of this feeling would be political in expression if not in origin. Unless the appropriate Minister were prepared to take the fullest responsibility for it, stand wide open to criticism of all kinds, and entertain willingly and positively every suggestion for improvement, the board would not live a month.

If, then, it is a fallacy to suppose that a corporate body created for this purpose could shelter behind its "independent" status, its creation would have to be justified on the ground that it would be likely to build and run a comprehensive national medical service more satisfactorily than a Government Department could. On this question there are two powerful and conflicting bodies of opinion. The advocates of the corporate body point to the shortcomings of Government Departments: their lack of initiative, their arrogance, dilatoriness, ignorance of real life, complacency, excessive centralization, parsimony; and other faults from which Departments suffer. They point on the other hand to the boldness, originality, and efficiency with which the London Passenger Transport Board, the B.B.C., and the War Agricultural Executive Committees have overcome difficulties, and the flexibility with which they tackle new problems and meet new demands. The advocates of the Government Department condemn the tendency of the independent and irremovable board to ignore or resist popular feeling, and its insulation from Parliamentary influence over such matters as its treatment of staff; they brand its relative autonomy as hostile to democratic principles, as the thin end of a Fascist wedge. They declare, moreover, that whatever may be said for "public" quasi-commercial services such as electrical supply and broadcasting, "social" services paid for by the State cannot be fittingly handed over to an autonomous board but should be run by a Department under a Minister fully responsible to Parliament. They assert that a Minister is able under the present departmental system to find sufficiently talented and creative persons within the Civil Service, and that he may also bring anyone he pleases into the Department *ad hoc* from outside; he may if he likes form them into a board, as in the Defence Departments or the Post Office, or he may adopt some other means of co-ordinating their work. These partisans of departmental enterprise point to the efficiency of the Post Office, the Stationery Office, the Children's Branch of the Home Office, and many other Departments.

¹ *The English Constitution*, p. 189.

The truth is probably that in running a social service far more depends upon the personal qualities of the administrators and far less upon the mechanism than is usually admitted. But the fact remains that on two occasions the Representative Body has voted in favour of a public corporation as the most satisfactory form for the central administration of medical and health services. The debate on this last week brought forth the highest level of utterance of the whole meeting. Those present listened with sustained interest. It is clear that behind the approval of a public corporation lay a deep-felt distrust of an unreformed Ministry of Health. And this was itself based on a still deeper distrust of the influence of party politics on the development of medicine, and also of the effect on it of the civil service mind and procedure. It seems clear that, until this question of central administration is settled to the satisfaction of the medical profession, no Government will be able to count upon the whole-hearted co-operation of the doctors of this country in working out plans for the development of a comprehensive medical service.

RESEARCH IN OPHTHALMOLOGY

As announced in the *Journal* of Sept. 18 the University of Oxford has launched an appeal for funds for the foundation of a Department for Ophthalmic Research after the war. This is an event of real significance deserving of every support. There is no doubt that during the last generation British ophthalmology has by no means distinguished itself in academic fields, however good it may have been in the practical side of the work of its exponents. Previously—indeed, ever since the study of the diseases of the eye had become a specialized branch of medicine in the middle of last century—the names of British pioneers were always of international repute; to-day these are the exception and the output of fundamental research has been scanty. It may be that to some extent this is explained by the fact that ophthalmology offers a ready economic opportunity to the newly qualified medical man because of the ease with which he can slip into the routine work of well-paid refraction clinics and thus can side-step junior hospital appointments with their facilities for research. But to a greater extent it is probably due to the undoubted dearth of the stimulus and opportunity for ophthalmic research in this country to-day.

There is no question that the problems awaiting solution in ophthalmology are many—in physiology, pathology, and therapeutics. The present appeal for funds for Oxford is addressed in the first place particularly to the industrial community, and it is obvious that the returns ophthalmology can give to industry are large. Most obvious is research on the prevention and cure of industrial diseases, particularly in such trades as chemicals and engineering. Mining is another example: thus recent research on the action of certain sulphonamides on infections of the cornea resulted in the hypopyon ulcer so commonly met with in miners becoming an out-patient incident instead of an extremely serious disease usually leading to much permanent incapacity; while improved lighting has reduced to a very considerable extent the drain on the mining industry caused by heavy compensation for miners' nystagmus. Less obvious are the very great problems of factory illumination, a factor in industrial efficiency much neglected in this country, the value of which can be appreciated only by those who have experienced the increased output and improved morale which follow the application of scientific principles to the problem. Commercial aviation, moreover, involves a multitude of problems yet unsolved. It is interesting that a very large amount of yet unpublished research has been going on continuously since the war

began to meet demands of the most varied nature in the three Services; few of these problems are not met in some degree in times of peace, but hitherto it has required the urgent stimulus of war to excite active response to hasten their solution. The financial returns of such policy carried on in normal times would be large. In this country four and a half million pounds are spent annually on the mitigation of the distress caused by blindness: the spending of a quarter of a million on the endowment of research as is asked by the University of Oxford may do not a little to reduce this bill, not to speak of the potentialities it may have as an investment in industrial progress.

If it is for the lay community to provide the opportunity it is for the medical community to provide the stimulus and the spirit. The time is past when advances in knowledge could be attained by relatively simple methods of a single investigator; the great complexity of the problems now awaiting solution demands ever-increasing complexities in technique and ever finer methods of analysis which can be met only by a team working in close liaison with a whole congeries of related branches of science all working under a similar inspiration. Ophthalmological research must concern itself with the problems of biophysics and biochemistry, of physics and physiological optics, of pharmacology, bacteriology, and pathology, of embryology and genetics as well as of general medicine and surgery, and their investigation requires the laboratories of a university as well as the beds of a busy general hospital. In this country to-day there is only one university chair in ophthalmology—that at Glasgow. Oxford would be an ideal centre for teaching and research in the Provinces. The related sciences are fully represented and the atmosphere is pregnant with the spirit of research. A large general hospital is available, and next door to it and in close relation with it the Oxford Eye Hospital (due to be rebuilt through local appeal) still has the tradition of Menteith Ogilvie and Robert Doyne. Moreover, under the proposed regional scheme of the Joint Hospitals Board this hospital will assume greater importance by becoming the regional centre for the counties of Oxford, Buckingham, and Berkshire for ophthalmic work and teaching. To complete the scheme for the whole country, and to allow British post-war ophthalmology to assume its rightful place as a leader of progress throughout the Empire at the world, there remains to establish similar research and teaching facilities in London. It is to be hoped that this will not be too long delayed, though perhaps it will await the co-ordination and encouragement expected from the Goodenough report.

LORD DAWSON OUR PRESIDENT

The death of Sir Beckwith Whitehouse on July 28 in the British Medical Association without a President at the time (through the dislocations of wartime) without a President-Elect. In this unforeseen situation the Executive Committee took a bold and imaginative step. It proposed that Viscount Dawson of Penn, our President at the Centenary Meeting of 1932, and an old and tried member of Council should be asked once again to wear the badge of office as titular head of the Association, this time not in an atmosphere of ceremony and rejoicing but in hard days of warfare and professional crisis. The Council with one accord approved this recommendation on the morning of September 21 and passed it on to the Representative Body, which less than an hour later unanimously elected Lord Dawson as President for 1943-4. On September 22 at the statutory Annual General Meeting of the Association he was inducted to the vacant chair and gave the address which we print at page 429 this week. Before the end of the

Lord Dawson had applied himself whole-heartedly to future of medical and allied services, and his idea of shape of things that might befall ran through the pages he report of the Consultative Council to the Minister of Health, of which he was chairman. That report languished 20 years in departmental files, even though in 1930 B.M.A. put forward publicly its proposals for a general dental service for the nation, and later revised and ended them. Again, at the close of 1940, the B.M.A. like once more into the long silence of Whitehall, and Medical Planning Commission which was then set up to the advantage of Lord Dawson's help as one of its vice and most influential members. The Interim Report of the Planning Commission and the Beveridge Report, which is to be followed now by the Government White Paper, have brought the whole matter into the forefront of dental politics and economics; and it can but be echoing the voice of the 44,300 members of the Association to say how fortunate we are to have the senior medical spokesman as our President in the difficult year to come.

ANILINE INTOXICATION

Aniline, like many other amido- and nitro-compounds of benzene, has long been known to cause symptoms of intoxication associated chiefly with its capacity for producing methaemoglobin. But this question of methaemoglobinæmia has been a matter of much discussion and controversy. While some authorities have been able to demonstrate its presence in man and in the dog—an animal known to form methaemoglobin readily—others have failed to produce it in other animals. Similar disagreement has arisen about the exact cause of death in acute aniline poisoning, whether from cardiac failure or from respiratory depression. A recent series of experiments¹ on dogs, with varying dosage and speed of administration of aniline, have gone far to solve many of these problems.

Briefly, it appears that aniline exerts its toxic action in two ways: first, indirectly, by the production of methaemoglobinæmia, with the consequent effects of oxygen deficiency on the various physiological systems; second, directly, in conditions of high concentration, by circulatory depression and cardiac arrhythmia. The formation of methaemoglobin is a direct effect not of aniline itself but of its conversion into an "active" compound, probably aminophenol, which forms methaemoglobin almost instantly *in vitro* in the presence of oxygen and very rapidly *in vivo*. One of the most striking features of the administration of aniline to dogs in these experiments was the "time lag" in the accumulation of the maximum methaemoglobin. Thus, administration of 10 mg. of aniline as a 2% solution in saline produced the maximum (about 20%) of methaemoglobin in two hours, while increasing the dosage up to 100 mg. resulted in a progressively greater methaemoglobinæmia (up to 70%) in periods of eight hours. That this time lag was not entirely due to the time required for absorption was shown by a similarly marked delay after intravenous administration. It is suggested, therefore, that the delay represents the time required for the conversion of aniline into the active agent, and that this is probably a catalytic effect. The most important effect of methaemoglobin anoxia is a progressive depression of the brain, and neurological signs appear when the methaemoglobinæmia is 55 to 60%, and unconsciousness at 70 to 75%.

Cardiac arrhythmias and circulatory depression are believed to be chiefly a direct aniline effect, though

methaemoglobin anoxia, which also depresses the vasomotor centres and myocardium, demonstrated by fall of blood pressure and changes in the electrocardiogram, was undoubtedly an additive factor in their causation. Smaller doses of aniline were found to cause transient central nervous and circulatory stimulation, due primarily to action on the central nervous system: very large doses caused respiratory and circulatory depression, the latter due primarily to action on the heart.

MANIPULATION OF BIRTH-WEIGHTS

Some weeks ago Dr. Letitia Fairfield drew attention in our correspondence columns (June 5, p. 706) to the practice of some midwives of making a routine deduction of four ounces or some such amount from the birth-weight of infants "to allow for the cord and meconium." This practice has been carried out in a number of maternity units without the knowledge of the responsible medical staff and sometimes without the knowledge of the matron or sister-in-charge. One domiciliary midwife employed by a local authority has explained that her custom has been to deduct nothing for stillborn or premature infants, but to take three ounces off babies of over five pounds in weight at birth, and to use her discretion in taking off more if the baby is very big. The reasons given for the practice are mainly two. The first is to avoid the worry which a fall in the baby's weight after birth is likely to cause to the mother. As to this it would surely be simpler for the midwife to reassure the mother by explaining the facts to her rather than to falsify the figures. The second reason is a more reprehensible one—namely, that the practice defeats an inconvenient hospital rule whereby babies are required to regain their birth-weight before discharge.

The Central Midwives Board has now been apprised of the practice and has issued a circular to the training schools stating that the Board requires the midwife to keep accurate and detailed records, and that the practice of making these deductions, besides being a contravention of the Board's requirements in this respect, makes the records valueless for the purpose of comparison and research. The attention of all midwives in the training schools is accordingly being directed to the requirement that the exact birth-weight shall be recorded as well as the exact subsequent weights. The Board's circular, however, will not necessarily reach midwives who are not attached to the training schools, and there may still be some difficulty in disposing of what seems to have become an occult professional tradition, to be conveyed from teacher to pupil, or from midwife to midwife, in a whisper, perhaps with some secret enjoyment at the idea of befooling a paediatrician who thinks that all infants should make arithmetical progress from birth onwards. It may be argued that the only harm done is in the field of statistics and records, which some midwives may regard as merely material for pigeon-holes. But the fact is that statistics is the groundwork of research, and in this instance certain theories regarding the feeding and care of infants have been built upon the weight chart without any idea on the part of the members of the medical profession concerned that in many cases the birth-weight had been marked down by 5% or so.

Presumably the light now thrown on the subject by Dr. Fairfield will lead to the abandonment of the practice so far as midwives employed in hospitals and maternity homes are concerned, but it may not be so easy to control the reckonings of the domiciliary midwife, who attends nearly two-thirds of the confinements in this country. A doctor called in by such a midwife might be well advised to ask her whether the weight chart owes anything to

¹ Clark, B. B., Van Loon, E. J., and Morrissey, R. W., *J. Industr. Hyg.*, 1943, 1.

imagination. Meanwhile one particular inquiry which was based upon 5,000 birth-weight records is wasted, and we are left wondering whether any other secret understandings lurk among those on whose indispensable and usually most efficient and loyal work the members of the medical profession have to rely. Is the temperature chart exempt from manipulation? This revelation concerning midwives is disconcerting not only because a good many carefully collected and collated statistics are vitiated but because it suggests a certain irresponsibility on the part of some women who enjoy the status of a profession and should be mindful of its obligations, and also because it discloses a failure on the part of the defaulting midwives to realize why babies are weighed or why records of weight are kept at all.

CO-OPERATIVE ANTIMALARIA WORK IN BENGAL

Perhaps owing to insufficient publicity the ordinary medical man in this country has little idea of the very considerable and highly developed organization which exists in India for the control of malaria in that country. In the first place, and naturally the most important, there is the Government organization against malaria which includes besides the different Provincial organizations or malaria departments under each Province and the malaria organizations of the great municipal cities like Bombay, the Central Government organization, the Malaria Institute of India, a great centre of research and control which is not only itself responsible for such huge antimalarial operations as those now being carried out at Delhi, but which advises and assists directly or indirectly almost every antimalarial activity throughout India. There is the excellent work of the Ross Institute carried out especially in connexion with the tea and other industries in Assam and South India. There are important and far-sighted field investigations under the Rockefeller Foundation. Nor does this exhaust the list, for there are many local activities of various kinds, among which may be mentioned a very interesting development in the rural districts of Bengal—viz., the Central Co-operative Antimalaria Society, Ltd. (of Bengal), which has now published its annual report for the twenty-second and twenty-third years of its existence. This society is probably unique of its kind. Bengal has an area about equal to that of England and Scotland, with a population, the densest in the world, of ninety millions. This population is mainly rural, living in scattered villages in country which has ever been the despair of the malariologist, since not only is it in parts an almost uninterrupted sea of riceland but it has become notorious for its malarious decaying rivers and their associated kaals and swamps, an expression of slow secular changes in the great Ganges delta. The Central Society with its 3,000 or so affiliated village antimalarial societies is, as its name implies, of a co-operative character, and it is closely linked with other co-operative activities. One of these, whose annual report was forwarded with that of the Central Society, is the Bengal Co-operative Home Crofters' Association, Ltd., a body which has as its object improvement of malaria indirectly through increased interest of the antimalarial societies and their individual members in intensive cultivation of land about the villages. None of these societies possesses large resources, and the main purpose of the Central Society is not so much to carry out large-scale operations itself, for which it has not the funds, but to create interest in antimalaria work in the villages, especially among the villagers themselves, and to push for urgently needed work in the direction of opening out and keeping clear dead river channels, draining or otherwise dealing with de-

pressed areas and other conditions requiring improvement. It is clear from the reports that the Society's activities have the sympathy and support of many influential persons in Government, and it is to be hoped that a bid of this kind towards self-aid will receive the financial and other help which its meritorious objects deserve.

HEALTH OF HOSPITAL NURSES

A high standard of health supervision of nurses prevails in some hospitals, and for serious illness hospital nurses invariably receive medical and nursing care of a high class. But there is no generally accepted standard for the supervision of nurses' health. The requirements concerning medical examination of student nurses before admission vary at different hospitals, the practice with regard to immunization follows no general rule, and the keeping of health records is defective. A committee of King Edward Hospital Fund for London, under the chairmanship of Sir Charlton Briscoe, has drawn up a memorandum with a view to securing an agreed minimum standard of health care.¹ The outstanding recommendations are that a physician should be appointed for the nursing staff, his responsibilities not to be limited to the treatment of the sick but to relate primarily to the maintenance of a good standard of health; that hospitals should require a detailed medical certificate with full family history from a nursing candidate's own doctor; that there should be a medical examination, with x-ray examination of the chest and haemoglobin estimation, either shortly before or on admission; that such examination should be repeated within six months of entering the preliminary training school, at the end of the first year, and afterwards annually; that full records of these examinations, and of the nurse's weight taken quarterly, should be kept by the physician to the nursing staff; that no candidate should be accepted for training or taken on the nursing staff unless she has been vaccinated against small-pox, and that immunization against diphtheria—at present obtaining in only about one-quarter of the training schools in the King's Fund area—should be the general rule at the start of training. The committee also commends to the medical and administrative staff certain suggestions with regard to nurses' diet, accommodation, and hours of duty. They should have three good meals a day besides tea. Each nurse should, if possible, have a room to herself with a floor area of at least 100 square feet. Baths and lavatories should be provided for the ratio of one to five or six nurses. The 96-hour fortnight should be the maximum in all hospitals. The practice of allowing girls under 18 to nurse cases of tuberculosis and other admittedly unsuitable conditions is deprecated, and the committee urges that the tendency in many hospitals to lower the minimum age of entry should be regarded as only a concession to existing circumstances. On the subject of a sick nurse the committee mentions that there is a complaint in some quarters about difficulties put in the way of nurses "reporting sick," and that there seems to be a general feeling among nurses that it takes a good deal of courage to report sick unless there is a high temperature or some other unmistakable sign or symptom of ill health. The committee suggests that it is a short-sighted and unwise policy not to ensure that even minor ailments receive attention at an early stage. Steps should be taken to encourage nurses to report as soon as they are not fit for duty. All nurses taken off duty should receive medical care immediately, and no nurse should be allowed to return to work until she has been passed as fit by a physician. A sick nurse should be set aside for the nursing staff.

MEDICAL SERVICE AND SOCIAL CHANGE: SOME REFLECTIONS AND CONVICTIONS*

BY

Viscount DAWSON OF PENN, P.C., G.C.V.O.
M.D., F.R.C.P.

President of the British Medical Association

Members of the Association.—Let me express the deep appreciation I feel at the confidence which you have reposed in me by making me your President at this time of change and stress. For my part, let me say that my sole reason for accepting the honour is the hope that I may be able to make some solid contribution to the solution of the difficult problems which beset equally the public and the profession and which can be solved only by friendly co-operation.

Before moving to business it is meet that I should make reference to the great loss incurred by the death of Sir Beckwith Whitehouse, who was not only a distinguished leader in gynaecology but who gave so freely of himself to the welfare of the profession and the public.

Concerning the subject which is foremost in all our minds, I think I would be serving you best if I were to speak with freedom and detachment, leaving you to do the same, so will you permit me to give utterance to certain reflections and convictions, limited though this must be by the time at my disposal.

The General Picture

I will, with your permission, say a word or two on the general picture, because, after all, medicine does not stand alone: it stands in relation to the whole social organism. An upheaval at once so vast and universal as this war must result in changes in the texture of civilization, and these changes will, for the most part, be those already in seed or in bud and waiting for some impetus to bring them to fruition. Land tenure, planning for town and country homes, industry, social security, health, and education afford examples, and there seems to be a common line of thought running through these projects—namely, that the community as such must, in varying degrees, form a partnership with individual effort so as to give direction and equality of opportunity without blunting the enterprise and zest of the individual to think and strive for the benefit of himself and his kind and thus preserve to personality freedom and scope.

If, in that partnership, the scales are weighted too much in favour of community direction, the result will be regimentation and a deadening uniformity, and if weighted too much in favour of individualism the result will be a haphazard and uncoordinated service. It is the task of statesmanship to find the mean.

I pass to another reflection. The progressive quickening of the social conscience is an outstanding feature of this century, and it has found expression in the humanizing of industry and in a body of social effort without precedent and a body of legislation to improve the health and welfare of the people. But if we pause to inquire whether the achievements of social reform between the last war and this, as judged by the removal of social inequalities and the establishment of social justice, were effective, our answer would have to be in the negative. I need but instance housing, social security, medical services, and education; there has been and there still is a sense of frustration in the community.

A Medical Service for All

To focus on our special concern, is it not a reproach, in view of the way medical knowledge has marched ahead, that a corresponding health and medical service has not been rendered available to all citizens long ere this? In this connexion the pioneer efforts of the medical profession stand forth to its credit, and I am going to stress that historical truth. From 1920 onwards it has, through various agencies, successively and consistently advocated a comprehensive medical service and

co-operation between local authorities and voluntary hospitals and agencies. The latest of these efforts is the Medical Planning Commission—a widely representative body.

In contrast, the Ministry of Health, from the death of Sir Robert Morant in 1920 to nearly the outbreak of the present war, has cold-shouldered or opposed any such suggestions. It is only fair, however, to add that those many years of obscurantism have given place at the Ministry for two or three years past to enlightened co-operation, and let me say further that the present Minister, who is greatly interested in this reconstruction, has repeatedly stated that this comprehensive service should be a partnership between the local authorities and the voluntary hospitals, and that in the administration of such a service doctors would play an important part.

Since the Interim Report of the Medical Planning Commission saw the light of day the Beveridge Report on Social Security has come into the picture. Most of us would say that greater security against want is socially just, but the social security scheme postulates Assumption B, which is concerned with a nation-wide comprehensive health service. The inference is that the foundation of such a service is an accepted policy and, incidentally, it has wide and strong popular support.

Misunderstanding and Criticisms

I come to a matter which has troubled me much recently. In recent weeks there has been public misunderstanding because discussion about the form of the service has been interpreted as opposition to its foundation, and this has led to a considerable amount of criticism of the profession, which shows at present little sign of abatement. An illustration has arisen from the motion passed at yesterday's meeting, when by a large majority "a whole-time salaried State Medical Service" was rejected. No fewer than three intelligent people said to me last evening that they were surprised to see that the Representative Meeting had, after all, voted against a "State Medical Service," which is quite a different proposition, for it is impossible to carry out Assumption B without the State having a general direction.

'Needless to say, in the shaping and organization of the service, doctors must rightly have a big say; after all, they have to work it; they know the complexities of medical practice, and they, with the public good in the forefront of their minds, and subject to the authority of Parliament, must carry a leading responsibility. Be it remembered that the changes in medical practice to be wrought are deep and fundamental and will affect all members of the profession; no other nation, comparably placed, has undertaken so big an endeavour. Is it not obvious, therefore, that this service must be built up in stages, in accord with the Prime Minister's Five-year Plan? Foundations first. If you will permit me I will now pass to consider one of those foundations.

Any service needs administrative direction. The British Medical Association is an example. If properly designed, that direction will not interfere with our freedom, and the Minister has promised that the profession shall have a large share in such administration. What, then, is the best form of local administrative body for this service? That, after all, is the prerequisite to any action of any kind and has to be settled first. Should that local administrative body be the major local authorities, or a joint board embracing several major local authorities with vocational advisory bodies attached—and this latter is an essential condition—or should there be large areas specially delineated for health purposes, each administered by a widely representative Health Council? The last idea is, to my mind, the most far-sighted and attractive proposition. Both for the public and for the doctors it offers the best prospect of future development.

I hope the Government will give it favourable consideration; but we must remember this—that the Minister of Health is between the upper and the nether stones. On the one hand he has to pay attention to the medical profession and wishes to do so, but, on the other, he has to carry along with him the local authorities. It may be that local authorities would not be too eager to agree to the larger plans which I personally would favour—namely, "health provinces" administered by a representative Health Council.

* A brief address on his election to the Presidency of the Association at the Annual General Meeting on September 22, 1943.

A Comprehensive Service

I pass to my next point. In the light of Assumption B the Beveridge report leaves to the medical profession and the community the devisal of the comprehensive service. The social security payment for sickness is only a maintenance payment, and the Beveridge report favours voluntary insurance to be "jam" for the "bread." Here contributory schemes would provide amenities according to the taste of the patient. Supposing a grocer who by his industry has become a successful man wants to provide his sick wife with the comforts of a room in a pay-block, is he to be denied that privilege? The service of medicine needs to be infinitely flexible. Man sick is individualistic, and let us beware of the doctrinaires who think in terms of tyrannical uniformity—one of the faults of the Nazi creed. We want the same essential service for all—namely, the best—but no dull uniformity with it. A comprehensive service, free to all citizens, does not necessarily involve a whole-time salaried service for all doctors, nor is it incompatible necessarily—I am not saying desirably—with private practice and pay-blocks. Although, in my belief, more earnings in the future will be derived from salary and less from fees, I am far from convinced that any uniform system of service or payment will meet conditions so multifarious as those attaching to medical practice, and any emergence of official and non-official groups of doctors would, in my opinion, be disastrous.

We must recall that one of the evil consequences of the Ministry of Health not accepting the advice of the leaders of the profession in 1929 was that they thereby instituted in any one town two sets of hospitals and two groups of doctors. If they had then accepted advice and instituted machinery for progressive co-ordination of local government and voluntary services we should be much nearer our goal to-day.

Fortunately, we now have at the Ministry of Health a different order; it is co-operative and anxious to work with the profession. Payment by salary, by fee, by capitation grant, separately or in combination—these admittedly thorny questions can find their solution only in the light of experience.

In conclusion, any satisfactory scheme for a comprehensive medical service can be built up only in stages: foundations first and soon, superstructure later and gradually in the light of accrued experience. Such experience could be obtained by different "try-outs" in different regions during an experimental period, and that applies, for instance, to health centres. Customs, habits, feelings, many of them centuries old, must not be suddenly uprooted; rather must the new order be gradually grafted on to medicine's historic past. Such is our English way. So following, not otherwise, when its reorientation reaches its completion, medicine will have become greater in its comprehension, and will offer to its disciples a life of fullness and content and to the people a steadily enlarging prospect of health and welfare.

Reports of Societies

LABORATORY CONTROL OF ENTERIC FEVERS

At a meeting of the Fever Hospital Medical Service Group of the Society of Medical Officers of Health, with Dr. ANDREW TOPPING in the chair, Dr. A. FELIX opened a discussion on recent advances in the laboratory control of typhoid and paratyphoid fevers with an account of the theory and practice of typing typhoid and paratyphoid B bacilli by Vi bacteriophage and the Vi agglutination tests in the detection of chronic carriers. He said Craig and Yen (1938) found that strains of the typhoid bacillus could be divided into a number of types on the basis of their sensitiveness to specifically adapted anti-Vi bacteriophages. The results of the typing by this method were as reliable and significant as those obtained in streptococcal or pneumococcal infections with the old-established serological tests. More recently Felix and Callow (1943) found that the bacteriophage technique could be applied also to strains of the paratyphoid B bacillus. Anti-Vi phages of *Bact. paratyphosum* B could be adapted to develop a high degree of specificity for particular strains, whereas anti-O phages were incapable of such adaptation. So far four different

Vi-phage types of *Bact. paratyphosum* B had been identified and more than 90% of the strains isolated from patients' carriers in Great Britain during the past three years were found to belong to those four types. This new typing method was an indispensable laboratory aid to the investigation of sporadic cases or outbreaks of typhoid and paratyphoid fever. The detection of a chronic carrier was usually a difficult task, though the methods of isolating typhoid paratyphoid bacilli had been greatly improved through introduction of refined culture media. In all the recent outbreaks of paratyphoid B fever in this country the individuals responsible for spreading the infection were temporary excretors. The true culprits—namely, the chronic carriers—escaped detection. The Vi agglutination test, which originally applied typhoid alone, had now been extended to paratyphoid B. Dr. Felix gave tables showing how this test could be used to help detect chronic carriers among recovered patients, who otherwise might be discharged from hospital because they excreted bacilli intermittently. A decreasing Vi titre would indicate temporary excretion, and a steady or rising Vi titre a possible chronic carrier state.

Application in Field Studies

Dr. W. H. BRADLEY said that since Budd of Bristol recognized typhoid as an alimentary infection in the middle of the 19th century enteric fever had been split up into a number of groups: first, by the identification of the typhoid bacillus Eberth in 1880, and then by the recognition at the turn of the century of the para-organisms and the other salmonellas. Next, by the application of the power of certain bacteriophages to lyse the organisms of typhoid and paratyphoid, it was possible further to classify them into a number of "phage type" groups. Illustrating the use of this in epidemiological field studies, Dr. Bradley said that a number of cases of typhoid which appeared in a cathedral town in the South-West would have defied investigation had it not been found that they belonged to three different phage types; when studied they proved to originate in three separate sources of infection operating simultaneously. It was possible to trace these sources to separate foci outside the city. More recently, fourteen cases of typhoid occurred in an extra-metropolitan borough using its own water supply, which naturally was suspected because an alternative common aliment could not be identified. The appearance of two cases of the same type in persons in a neighbouring locality who had not drunk the water helped to remove the suspicion. Dr. Bradley said it was usual for single cases, apparently sporadic, to occur in a London borough from time to time. For example, although there were only about 50 cases of typhoid notified in London in 1942 they occurred in 22 of the 28 boroughs. It was rarely possible to trace the source of infection or to relate cases in different boroughs. Since the beginning of 1943 they had applied phage typing to the problem. Up to June cases of typhoid had appeared in 16 boroughs; the majority had been related to three foci of infection; of the remainder two cases were imported, another arose in a mental hospital, and one only had proved resistant to investigation. He agreed with Dr. Felix that with careful persistent epidemiological inquiry and specialized bacteriology it should now be possible to account for almost every case and in time to eradicate completely the enteric fevers. Certain changes in current practice were, however, necessary. Previously the objective had been to obtain sufficient negative cultures to clear the patient; now blood, stool, and urine cultures were made repeatedly until the organism was recovered and typed. The organism from every sporadic case and from a sample of the cases in any outbreak should be typed. The date of onset should also be determined as accurately as possible and the medical officer of health who was investigating the source of the disease should be informed of this and the type of organism. There was some clinical evidence that organisms of different types differed also in virulence, and to some extent typing might be of value in prognosis. Vi determinations were useful in detecting carriers. As a preliminary screen for a carrier in a food-handling establishment for instance, the Felix Vi test simplified investigation; taken in conjunction with the evidence obtained from circumstantial inquiry this screen made much of the stool and urine cultures unnecessary, and, what was more important, gave a prompt and more dependable answer.

Discussion

Dr. R. CRUICKSHANK thought that the crux of the situation was the chronic typhoid carrier. Recovery of typhoid and paratyphoid organisms, either in the acute stage of the disease or in convalescence, demanded selective media. This was true over the whole range of bowel infections. For example, their se had demonstrated that convalescent carriers occurred after salmonella infections—a thing never suspected in the past when MacConkey's medium was employed. Dr. A. L. K. RANKIN, describing the clinical features in the small borough outbreak mentioned by Dr. Bradley, said that in the adult cases the onset had been gradual, but two children had gastro-intestinal symptoms. A characteristic of all cases was their mildness. During the stage of advance the temperature had shown morning remissions which he regarded as a good prognostic sign. Leucopenia was present in all cases. The diazo test was consistently negative, but no case was admitted before the 14th day of disease. One woman developed the uncommon complication of mastitis. Col. G. W. M. FINDLAY asked whether it would be possible to treat typhoid by phage given intravenously. Dramatic results had been claimed in India from the combined use of phage and typhoid antitoxin to deal with used products. In experiments on mice he had found it necessary to give phage very early to obtain a therapeutic effect.

Dr. BRADLEY, in reply, said that gastro-intestinal symptoms at the time of ingestion of typhoid bacilli were common: they had been encountered in both the Croydon water-borne and the Bournemouth milk-borne outbreaks. Intestinal symptoms consisting of the passage of blood and mucus were usual to begin with; vomiting came later. The whole upset was usually over in 48 hours. He described a hotel outbreak in which 36 guests had gastro-intestinal symptoms within 48 hours of arrival and 17 subsequently developed typhoid. Dr. FELIX suggested that the gastro-intestinal symptoms were not necessarily due to typhoid or paratyphoid organisms. They might indicate only that the vehicle was heavily contaminated with other organisms, including preformed toxins. He agreed with Col. Findlay that in the phage treatment of experimentally infected mice the results were good in typhoid, whereas no effect could be seen in *aertrycke* infections. This was probably due to the fact that typhoid was not a usual infecting organism in mice, whereas *aertrycke* was. He had used phage in large intravenous doses in the treatment of chronic typhoid carriers, but the experiment was a complete failure. Yet the same phages had been tested in broth and up to 50% ox bile, where they produced complete sterilization. He thought that phage treatment might be tried on carriers of shorter duration where there was less heavy damage at the local focus of infection.

to the above observations retention of salt and water would follow. I am therefore trying now the effect of urea administration in these cases; it is, of course, too soon to speak of results, but there seems a rational basis for this treatment.

My interest in the subject was increased by the paper by Drs. Beaumont and Robertson (*Journal*, Sept. 18, p. 356) in which they describe a syndrome of "pituitary hypothyroidism" in which, nevertheless, the patient was thin to a degree resembling Simmonds's disease. Here the urea clearance and water elimination were reduced. Sodium chloride, among other things, was given freely, and the patient improved. It will be interesting to see whether a disturbance of salt elimination has a definite effect on increasing or decreasing weight.

One other point, incidentally. Years ago Sir Robert Hutchison made the sage remark that protein is one of those things of which we must have too much in order to have enough. The tissues select those amino-acids most suitable for their needs from the welter of them resulting from tryptic digestion, so that a wide choice is advantageous, while the rejected fragments are excreted as urea. May it not be that the widespread complaints of muscular fatigue and twitches are due to the prolonged restriction of choice for muscular repair having a cumulative effect? The effect of a prolonged Chittenden diet is well known. My personal experience during a recent visit to Eire for academic reasons was that although I was working hard an ample meat diet corresponded to a notable diminution of muscular fatigue.—I am, etc.,

Cambridge.

W. LANGDON-BROWN.

Inadequate Hospital Diets

SIR.—Your leading article (Sept. 18, p. 365) is most disquieting. It is scandalous to find in a London general hospital that: (1) the average daily intake of vitamin C was 3 mg.; (2) the nurses were not getting enough to eat and their diets were deficient in vitamins A and C. It is lamentable that improper feeding in hospitals is still being perpetuated. I can recall while a resident in a London general hospital in the late 'twenties being given margarine (non-vitaminized), meat so tough and fish so putrid that we hurled them down the hatch to the kitchen below. The patients' food was fit only for the pig-swill. The official reply to our complaints was that if the residents were better fed then the nurses' diet would have to be improved, with concomitant increase in the cost of hospital maintenance. It is relevant that in Sir Robert Hutchison's own hospital the residents' mess was the envy of all others. You say, Sir, that the hospital kitchen is at least as important as the hospital dispensary. I would up-grade the kitchen staff in status and salary to that of the operating theatre. Why are the numskulls put in the cookhouse? The Minister of Health is alive to the situation, and one hopes that all hospitals will implement forthwith the valuable advice given in the brochure *War-Time Feeding in Hospitals*.

Again you are right when you plead for the hospital-dietitian being in full control of the kitchen. She must be on top and not on tap, and the steward should be subservient to her. When will medical and lay committees appreciate that proper feeding of all within the confines of the hospital makes for quicker convalescence, better service, and a happy and healthy community?—I am, etc.,

London, W.1.

W. C. W. NIXON.

Correspondence

Urea and Water Metabolism

SIR.—I was much interested in Dr. J. A. Brown's article on urea for migraine (Aug. 14, p. 201), though from a different angle. Since the war I have been greatly struck by the number of girls, both in the Services and out, who come complaining of increasing weight, which has proved entirely refractory to thyroid. In one such case 20 gr. of desiccated thyroid had been taken daily, and on stopping this she only increased 2 lb. a month, so it was clearly contraindicated.

Naturally, one may attribute a good deal of this to the large starch content of war diet; active life makes them sufficiently hungry to eat much of the only food which is plentiful. But in a good many cases the weight has either increased so rapidly or has fluctuated so widely that it seemed to me there must be a disturbed water balance, presumably due to the pituitary, since they nearly all showed the limb-girdle type of obesity. I therefore prescribed mersalyl or aminophylline with restriction of salt intake, but with only varying success.

Dr. Brown refers to the observation of Goldzieher that in migraine there may be retention of 73% of a test amount of salt, together with water retention. It therefore occurred to me that the present low protein diet deprives the body of some of the normal diuretic, urea, since the greater part of this comes directly from the breakdown of protein; and according

Transfusion and Overloading the Circulation

SIR.—The very interesting paper by Dr. R. Drummond on the dangers of circulatory overloading (Sept. 11, p. 319) emphasizes the fact that on occasions over-treatment can be more lethal than no treatment at all. The efforts to save life by blood transfusion will achieve their greatest success only when the clinician in charge of a case can recognize the earliest warnings that the heart is being asked to do more than is within its power. Dr. Drummond quotes Sharpey-Schafer in support of his statement that the earliest sign of overloading is pulmonary oedema, as shown at first by the onset of crepitations. No mention is made of the importance of the pulse rate as a clinical guide. In my opinion it is the most valuable index of danger, and I am sure other observers can confirm my experience in this respect.

Patients in whom haemorrhage is associated with toxæmia, as in severe concealed accidental haemorrhage, well illustrate

the type of case to which Dr. Drummond referred as being particularly liable to react adversely to circulatory overloading. For some years it has been my practice in transfusing these and similar patients to keep an almost continuous observation of the pulse rate, and to record it every few minutes on a chart at the bedside. As the patient improves the rate falls and the volume increases. When in spite of an apparent improvement in the general condition of the patient the pulse rate commences to rise again, the transfusion is slowed or stopped, and within a few minutes the rate again falls. I have been able to demonstrate dramatic responses of this type on several occasions when transfusing desperately ill women. I do not know as yet whether alteration in the pulse rate is an earlier sign than the onset of crepitations, although I believe it may be, but I am certain it is a more important clinical sign in that it is so easily elicited without disturbing a gravely ill patient in whom crepitations may well have been present before the transfusion was commenced.—I am, etc.,

Oxford.

JOHN STALLWORTHY.

Arterial Embolism and Crush Syndrome

SIR.—Uraemia following arterial embolism as described by your correspondent Dr. Guthkelch (Aug. 21, p. 245) is not commonly recognized, and its mechanism is unknown. I have recently had a case of spontaneous femoral arterial thrombosis in which uraemia developed; myohaemoglobin was excreted in the urine, and the muscles at necropsy were blanched, resembling those of the crush syndrome. It would be extremely interesting if such cases could be investigated with this specifically in mind; whether a mild degree of uraemia is of frequent occurrence or a rare complication of embolism or thrombosis remains to be seen.—I am, etc.,

London, W.12.

E. G. L. BYWATERS.

Treatment of Septic Hands and Fingers

SIR.—At this phase of the war, when every man-power hour is precious, it might well repay the Ministries of Health and Labour to circularize every doctor in the country with a short and concise bulletin on the treatment of septic processes of the hands and fingers. It is a matter of common observation that there is much unskilful and even negligent treatment of "septic fingers." The cost to the country in reduced production, sick benefit, and compensation must amount to hundreds of thousands of pounds every year. This, serious enough in peacetime, may prove a menace just now.

The greatest need is to revise our methods as they affect the students. In many of the teaching hospitals the most junior house-surgeons and students are in almost sole charge of the septic cases save for the nominal supervision of one of the surgeons. The latter will often only see these cases when they become so bad that admission is necessary. The supervision of the ripening stage is in the hands of the least experienced of the hospital staff. When incision is indicated the same functionary or, at his discretion, one of the senior dressers, performs the operation under nitrous oxide administered by the most junior anaesthetist or his student deputy. The results of this surgical team work can be seen in large numbers every day in out-patient departments, where the patients attend for hot soaks, probing, and re-incision.

The newly qualified doctor starts in a house job or, worse still, in general practice with some fixed and some confused ideas on the subject. The fixed ideas are based on his personal observations and generally include the following: (1) Septic fingers are the prerogative of the inexperienced surgeon and are seldom taken seriously except by the patient. (2) Septic fingers provide the embryo anaesthetist with excellent and varied material for short administrations of nitrous oxide with, or more often without, oxygen. The absence of the latter may be very noticeable. (3) Septic fingers are invariably chronic cases and too much improvement must not be expected at once. (4) The after-care involves hyper-ionic soaks, radiant heat, probing for sequestra, and much reflection and often regret that the initial incision was so small. (5) That someone called Kanavel has written a book on septic fingers which is generally acknowledged as the last word on the subject. Owing to its special nature, however, it seldom attracts the senior students, who are already overburdened with the more important issues of the after-treatment of gastrectomies and lobectomies, in which the examiners are more interested and on which the lecturers are more expansive.

The confused ideas concern the position and boundaries of the thenar space, the peculiar routes of the tendon sheaths, and the

multiplicity of most excellent incisions. On this type of experience the newly qualified doctor bases the treatment of his septic case in his general practice. Poulticing and the ripening process are a too often over-prolonged, osteitis develops, and stiffness follows. Because of hurry, incisions are too small and strategically badly placed. It is a defect in our legislation that to cut a septic finger under local ethyl chloride "anaesthesia" is not yet a criminal offence, and it is to be deplored that there are still qualified registered practitioners who attempt to do it.

Much of this could be corrected by giving prominence to real sound methods, such as are employed by some clinics. The method of the Birmingham Accident Hospital (at which I recently spent an instructive stay) seems ideal: The septic hand or finger is immobilized on a P.O.P. splint until it improves, as a great many do or until incision is indicated. When the latter is necessary the patient is admitted. Morphine and scopolamine are given 1½ hours before operation. The anaesthetic is pentothal, nitrous oxide oxygen, and, if more is wanted, trilene. The operation is in large theatre and performed by a surgeon of experience. Full aseptic ritual, as for a major abdominal, is observed. Operation is carried out in a bloodless field, secured by the routine application of a sphygmomanometer. The surgeon's need, not the volatility of the anaesthetic, determines the duration of the operation. The same care is given to a septic finger as would be given to a compound fracture of tibia and fibula. Finally, the incision is very lightly packed with vaseline gauze and the limb again immobilized in P.O.P. Hot fomentations are not used, and dressings are infrequent. Rehabilitation is started at the earliest moment, and after-care is not less than care at operation.

No doubt in the future penicillin will banish the bogey of the septic finger, but in the meantime it remains as a great menace to industrial efficiency, and correct treatment by sound surgery and skilful after-care will only become standardized by propaganda on a big scale. It cannot be over-emphasized that a septic finger can be just as incapacitating as a fractured humerus or even femur, and cause nearly as much incapacity and loss of working time.

—I am, etc.,

St. Ives.

E. C. ATKINSON.

Treatment of Lupus Vulgaris

SIR.—I think the annotation headed "Treatment of Lupus Vulgaris" (Sept. 18, p. 366) calls for a few comments. In the first place the Finsen and Finsen Reyn lamps have been abolished as obsolete from the London Hospital since February 1938. The old Finsen lamp needed the attention of one nurse per lamp, and treatment of each individual spot took, roughly speaking, one hour. Now the Finsen-Lomholt lamp is in use: three lamps can be managed by one nurse at a time, and commonly three treatments can be given in the hour on each lamp—a considerable saving. It is true that well-equipped and experienced centres must be maintained for the treatment of lupus vulgaris. Some provision also should be made for dealing with very advanced cases at suitable institutions, but the average case can well be treated at a lupus centre provided sleeping accommodation under suitable conditions is available at a reasonable distance from the centre. Such an arrangement should permit the patient in the majority of cases to continue work during the long treatment, to his own and the national advantage.—I am, etc.,

ARTHUR BURROWS.

Hon. Physician (with care of Out-patients)
to Skin and Light Department, London Hospital.

Issue of Radon

SIR.—The National Radium Commission and the Medical Research Council decided in January, 1943, that the following conditions should govern the issue of radon prepared from radium under their control. The same principles have been accepted by the London Hospital Radon Service and that of the Manchester Radium Institute.

1. It is the intention of the Radon Centres to supply radon only to hospitals which have been approved by the Radium Commission. Radon will not henceforth be supplied direct to individual clinicians.

2. The Radium Commission will in the first instance approve for supplies of radon only those hospitals which have a properly equipped radiotherapeutic department, with a radiotherapist and a physicist as part of the staff, and which have a properly organized follow-up of patients treated by radiotherapy. Such hospitals must undertake responsibility for seeing that the radon is properly used, with adequate precautions against wrong dosage.

3. Where members of the staff of an approved hospital carry out some of their work at other hospitals not able to comply with Condition 2 (above), they may obtain supplies of radon through the approved hospital provided that the radiotherapist of the approved hospital is satisfied that the radon is to be used under such conditions as will provide for efficiency.

Under these conditions the following hospitals have been approved to date—Sept., 1943:

Aberdeen Royal Infirmary	Marie Curie Hospital
Birmingham United Hospital	Middlesex Hospital
Bournemouth, Royal Victoria and	Mount Vernon Hospital and Radium
West Hants Hospital	Institute, Northwood
Bradford Royal Infirmary	Newcastle, Royal Victoria Infirmary
Bristol Royal Hospital	Newport, Royal Gwent Hospital
Burnley Victoria Hospital	Northampton General Hospital
Cambridge, Addenbrooke's Hos- pital	Norwich, Norfolk and Norwich Hospital
Cardiff Royal Infirmary	Oxford, Radcliffe Infirmary
Charlton Cross Hospital	Plymouth, Prince of Wales's Hospital
Edinburgh Royal Infirmary	Rochester, St. Bartholomew's Hospital
Glasgow Royal Cancer Hospital	Royal Cancer Hospital (Free)
Glasgow Royal Infirmary	Royal Free Hospital
Glasgow Western Infirmary	Royal Northern Hospital
Gu's Hospital	St. Bartholomew's Hospital
Hull Royal Infirmary	St. George's Hospital
King's College Hospital	St. Mary's Hospital
Lambeth and Hammersmith Hos- pitals, L.C.C.	St. Thomas's Hospital
Leeds General Infirmary	Sheffield Radium Centre
Leicester Royal Infirmary	Southampton, Royal South Hants Hos- pital
Lincoln County Hospital and Scunthorpe Hospital	Stoke-on-Trent, North Staffordshire Royal Infirmary
Liverpool Radium Institute	Swansea General Hospital
Liverpool Royal Infirmary	Tunbridge Wells, Kent and Sussex Hos- pital
London Hospital	University College Hospital
Manchester Royal Infirmary and Holt Radium Institute	Westminster Hospital
	Wolverhampton Royal Hospital

—I am, etc.,

GEORGE F. STEBBING,

Hon. Secretary, National Radium Commission.

Care of the Child's Eyesight

SIR.—The large sum which is to be devoted to research in ophthalmology at Oxford and to the prevention and treatment of eye diseases has caused much gratification and should bring great benefit to the public. In the meantime much could be done in the prevention of eye troubles at a very small expense. It has always seemed strange to me that, while children attending council schools have their eyes examined at regular intervals, there appears to be no routine examination of the eyes in public, preparatory, or private day schools, except in a very few instances. It would be simple for the visual acuity of these children to be checked twice a year; this could be done by one of the staff of the school with the aid of a Snellen eye chart, and no expert knowledge is required. Any child who did not come up to the normal standard could then be referred to an ophthalmic surgeon, and much valuable time would be saved. Under present conditions, if a child complains that he cannot see the blackboard, the master, instead of sending him straightway to an ophthalmic surgeon, usually tells him to go and sit in a desk in the front of the class, where the child is quite happy for another 12 months while the myopia steadily increases. Myopia usually comes on between the ages of 11 and 15 in those in whom there is a family tendency, and unless the child is examined twice yearly it is quite often unsuspected until the condition is fairly advanced.

I think the following three suggestions would do much for the eyesight of our future citizens: (1) That the visual acuity of all school children should be checked twice a year. (2) That they should work only in well-lighted class-rooms in desks suitable to their size so that they are always in the correct posture. (3) That no child should be allowed to read in bed except in the case of illness, when great care and attention should be given to the lighting.—I am, etc.,

Cambley.

LESLIE HARTLEY.

Health and Tonsillectomy

SIR.—In your annotation entitled "Health and Tonsillectomy" (Sept. 11, p. 334) you sum up by saying: "This study supplies additional evidence to support the view that a large proportion of the tonsil and adenoid operations in children are unnecessary." The "view" may or may not be correct, but I cannot find any support for it in the "study."

The compiler of the first series of statistics quoted by you states that "the tonsillectomized group had no advantage over the group who were not operated on," and most of the others

give expression to the same idea. But why should one expect to find any advantage? Why should any person who has undergone any operation have an "advantage" over another who has not required it?

Consider a single case. Johnny has had his tonsils removed and Tommy has not. In assessing the value of the operation we do not ask whether Johnny enjoys better health than Tommy or has any advantage over him. We ask whether he enjoys better health after the operation than he did before. Almost invariably the parents say that he does. I think that that is the only criterion by which the operation should be judged. The multiplication of the case by 100 or 100,000 does not make any difference to the validity of the argument. The only series of statistics in your list that has any real bearing on the question is that of the 364 boys whose sickness incidence had been studied both before and after operation, and in that series it is admitted that the operation was justified.—I am, etc.,

London, S.E.25.

ALEX ROSE.

Action of Pentose Nucleotides

SIR.—In the article on stimulation of leucopoiesis (Sept. 18, p. 365) there is the statement that pentose nucleotides "act mainly by redistribution and mobilization of preformed leucocytes." It would be valuable if the evidence for this statement could be published. My own experience does not support the contention. I find that, after starting treatment with pentose nucleotides, there is always a period during which no blood changes develop, however large the doses given. This period is about 4 days; and after its expiry there are immature granulocytes in the peripheral blood—a change that cannot be due to redistribution of cells already present in the circulation. In cases in which the treatment fails there are no such blood changes, and any explanation, other than that of new formation of cells in the marrow, must take these facts into account.—I am, etc.,

London, W.1.

A. PINEX.

Arsenic for Vincent's Infection

SIR.—I beg to disagree with Squad. Ldr. E. C. O. Jewesbury's statement in his article (Sept. 18, p. 360) that the employment of intravenous arsenical compounds for Vincent's infection is useless and wasteful.

As medical officer in the V.D. clinic attached to this hospital I have not infrequently seen cases of Vincent's gingivitis or stomatitis develop during arsenical therapy, although I cannot recall a case of faucial ulceration occurring under these circumstances. In most cases bismuth has also been employed, and may by irritating the gums be a precipitating factor in the onset of a Vincent's infection.

In my work in the fever wards of this hospital I again encounter Vincent's infection—cases admitted for diagnosis of diphtheria, or for treatment because of the severity of the condition. As I see all cases outside before admission, trivial or mild cases are not admitted. In those cases of acute faucial angina due to Vincent's organisms I have no doubt as to the efficacy of the intravenous administration of arsenic, as either N.A.B. or mapharside. Pain, fever, and malaise rapidly subside in the great majority of cases, and the local throat condition clears rapidly. I can recall only once having to give more than one injection. The gingivitis which often accompanies the faucial condition does not respond so well, and usually requires local treatment.—I am, etc.,

Isolation Hospital, Southend-on-Sea.

A. B. CHRISTIE,
Medical Superintendent.

The Common Cold

SIR.—The following facts may be of interest to either sufferers from or investigators of the common cold. During the course of twenty-five years' practice of psycho-analysis for the treatment of psychoneuroses I have observed that in them: (1) A cold invariably occurred in a particular emotional state. (2) The occurrence of a cold could be prognosticated whenever this state developed. (3) The cold could be aborted if a different emotional state could be produced in the course of treatment, or could be shortened if it had started. (4) Cold, wet, hunger, exhaustion, and a source of infection do not result in the development of a cold in the absence of the appropriate

emotional state. (5) Cold "prone" disappears completely as a result of successful treatment, and does not recur.

Though these observations have little immediate practical value, my experience demonstrates to me at least that the solution of the problem of the common cold lies in the sphere of preventive psychological medicine. The specific factor is psychological; the microbe one secondary.—I am, etc.,

E. WRIGLEY BRAITHWAITE,
Consulting Psychiatrist, Ministry of Health.

Sterility and Contraception

SIR,—In your issue of Sept. 11 (p. 350) Dr. Gibbon Fitzgibbon of Dublin questions the accuracy of the statement that contraception in nulliparous women is liable to cause sterility, and asks for further evidence of this. His request would seem most opportune, for there appears to be considerable loose thinking upon this subject. Very few authorities are teaching that contraceptive practice and sterility are related, but, should this tenet be true, it is clearly most necessary that the whole medical profession should recognize this fact and teach accordingly. For this reason a full discussion should be welcome.

Dr. Fitzgibbon finds that "the vast majority of causes of primary sterility are conditions which pre-existed marriage." Informed opinion would surely anticipate this conclusion. Mazer and Israel (*Menstrual Disorders and Sterility*, Heinemann) find that non-patency of the Fallopian tubes and faults in the seminal fluid are the two commonest single factors in the barren marriage. By no stretch of imagination could contraceptive practices bear upon these.

Doctrines which coincide with people's deepest superstitions, however unfounded, are always difficult to eradicate. From time immemorial the infertile woman has tacitly accepted her barrenness as a stigma and a punishment. It is a great responsibility, therefore, to play upon fears of this nature. The point is not merely academic. When the late Sir Francis Fremantle announced in Parliament that this alleged danger of contraception must be "preached from the house-tops" he must have brought grave anxiety to countless young married women, and may have caused many to renounce their Service jobs, or munition work, in favour of immediate pregnancy. If such teaching is true, only good can result. But at a time when the mysteries of sterility are beginning to be understood, surely the medical profession must shoulder the responsibility of agreeing upon such matters and giving concerted guidance upon them to the public.—I am, etc.,

London.

JOAN MALLESON.

Artificial Insemination

SIR,—I was interested in Dr. Mary Barton's letter (Sept. 4, p. 312), and while I do not wish to deprecate the value of scientific work on this subject, I feel that the procedure which she suggests where the husband has been proved the sterile partner—namely, the insemination of the wife with donated semen—is likely to worsen rather than improve the marital relationship, and is also handicapping unfairly the child born in this way. I shall deal with the psychological effects in each partner and on the child in turn, as I see them.

First, the mother. She is given the satisfaction of bearing her own child. Is Dr. Barton sure that this joy is sufficiently lasting and sufficiently embracing to give complete satisfaction to the mother, knowing that her husband was not the father? Was the donor carefully selected as resembling the sterile husband in appearance, or in character, temperament, and all these traits which attract a woman to a particular man? Have we any guarantee that the secret of the child's birth will be for ever concealed within the breast of husband and wife? Will the woman's love not tend to fix itself on the child and withdraw more and more from her husband, in spite of his generosity? Does the fact that she agrees to such a procedure not suggest that a child-fixation of her love and affection is almost inevitable?

Secondly, the husband, whom Dr. Barton seems to have left out of her calculations. She speaks of the "generosity" of the husband in giving his consent. I should rather use the expression "generous impulse," and I should fear that such an impulse in times of anxiety and trial would be perhaps bitterly regretted. I can see the sterile husband drifting away from his wife rather than being drawn closer to her by such a solution of their problem.

Thirdly, the child. Such a child would, in my opinion, be extremely prone to develop an Oedipus or mother-fixation complex.

To sum up. I am convinced that such a procedure would lead to a constant struggle, obvious or repressed, between the child, and the husband for the woman's love and affection. The effect of such emotional conflict seems to me fraught with danger both to the marital relationship of husband and wife and to that atmosphere of security and happiness in the home which is so essential to the development of a child's personality.

On the other hand, I feel that the couple who adopt a child by mutual consent, after the necessary investigation to make sure that the husband is permanently sterile, have a much better chance of achieving mutual happiness, and that the woman's maternal instinct can be satisfied, sublimated perhaps if you like, by the nurture and care of such a child, in a fashion more lasting than the thrill of the physical act of motherhood.—I am, etc.,

Falkirk, Stirlingshire.

ALEX. LEITCH.

SIR,—May I add to Dr. Barton's plea that careful consideration be given to and greater use be made of artificial insemination. Among its indications are: (1) impotence—more especially for the persistent case of premature ejaculation without penetration; (2) low counts containing some actively motile normally shaped sperms; (3) when the operation of epididymo-vasostomy is not desired or has proved unsuccessful in cases of double epididymal block. Here needle puncture can often obtain 0.2 or 0.3 c.cm. of fluid containing active spermatozoa. By replacing the puncture needle with a blunt Labat this amount can be inseminated without loss, giving the only possible chance of a family. In all these instances the husband's semen is utilized, and there can surely be no objection.

Selected donor semen, frequently that of the recipient's brother-in-law, at the request of and with the agreement of husband and wife, is more widely used in the U.S.A., where it has found much favour. In most cases it has prevented and not caused the drifting apart of two people, and has provided a child far more an integral member of the family than any adopted child would have been, and also satisfied a woman's yearning to have a child of her own.—I am, etc.,

London, W.C.1.

REYNOLD H. BOYD.

SIR,—To-day great interest is being taken in artificial insemination for married women. As yet I have not seen a discussion on its possibilities for unmarried women. Many of the latter do desire children and would be happier, and far less likely to develop into embittered spinsters, by realizing this ambition. The Church would surely be unable to frown on such a practice, as immorality is not involved. I think that the Government should give consideration to this question. Such offspring under present conditions would, I suppose, be regarded as illegitimate.—I am, etc.,

London, W.9.

ANNE ETHEL MCCANDLESS, M.B., Ch.B.

Penicillin

SIR,—Your interesting leading article on penicillin (Aug. 28, p. 269) contains the sentence: "The search for something else as good as penicillin but perhaps more easily produced has therefore failed, as have efforts to synthesize it." This statement is less than just to many first-class organic chemists at present engaged on attacking a problem essentially antecedent to that of synthesis.

Even though to the admiring medical practitioner the organic chemist may seem a wizard, he is not capable of attempting the synthesis of a compound until he knows its constitution. He cannot know the constitution of any compound until he has separated it in substantially pure form. Crystalline salts of penicillin, it is reported, have only just been obtained for the first time, and even these may well be less than 100% "pure." Hence characterization of pure penicillin has so far been out of the question. How much more so any attempt at synthesis! To say, therefore, that efforts to synthesize it have failed is not fair comment. To state, on the other hand, that its isolation in pure form has so far not yet been achieved is correct, and is undoubtedly due to the extraordinary chemical properties of this extraordinary product of an extraordinary organism.—I am, etc.,

Greenford, Middlesex.

A. L. BACHARACH.

Mosquitoes and Static Water Tanks

SIR.—Your observations (Sept. 11, p. 332) on a potential danger of the static water tanks becoming the birth-places of mosquitoes, especially of *Anopheles maculipennis*, are timely. Many years ago, when I was medical officer of health of Lahore (Punjab) (larger than Portsmouth and consisting of an interesting but very congested native city, a well-laid-out civil station, and certain villages in the outskirts of its boundaries), I made some investigations into the utility of certain small fishes as natural enemies to the larvae. I read a paper on the subject, as a delegate from the Punjab Government, at the All-India Sanitary Conference at Simla, and I took with me bowls of three species of fishes and larvae of *Culex* and *Anopheles* to show how voracious these fishes were in destroying the larvae, especially a beautiful specimen with golden bands on each side. The size of these fishes varies from one to one and a half inches. There must surely be in each country some species of fish which are natural enemies to these larvae. The best antimalarial measure would be the breeding of such species for this use. Oil has its limitations and is impracticable in some areas, and at present it cannot be used on a large scale.

The mosquito is mainly a nocturnal biting insect, and all through its life history shade plays an important part. The female by instinct seeks dark places to lay its eggs; so we find that inlets of the banks of streams with overhanging grass, reeds, shrubs, or trees are common breeding grounds. Thus it is not the size of the tanks which is a factor in the choice of a breeding place, but rather the position in which the tank is placed so that the water in it may be darkened by shade as by branches of trees above or by the side or sides of a building. Again, anything like leaves or algae will give a certain amount of shade and hiding place for larvae. I think it will be found that tanks out in the open, away from trees, hedges, or buildings, will not breed any mosquitoes. In my opinion, no static water tanks should be placed in a shade. If they cannot be removed the best plan would be to cover them with sections of well-fitting thin boarding, which can be rapidly removed when required. This will save nuisance, possible sickness, oil, time, and man-power. As oil acts mechanically by preventing air entering the breathing tubes of larvae it should not be impossible to find a chemical which would act as a larvicide. Where the eucalyptus tree grows no mosquitoes exist for long distances from them, and a few drops of eucalyptus oil on the pillow or handkerchief near by is a not unpleasant protection against mosquito bites.—I am, etc.,

Southsea.

A. G. NEWELL.

Pasteurization of Milk

SIR.—In recent discussions on pasteurized milk the following facts appear to have been overlooked. It is generally agreed that living tubercle bacilli in raw milk from tuberculous cows are responsible for a large proportion of cases of (a) intestinal and peritoneal tuberculosis, (b) spinal tuberculosis, (c) tuberculosis of other bones and joints, and (d) tuberculous glands. According to the Registrar-General's statistical reviews deaths from these forms of tuberculosis in 1921 were, respectively, (a) 2,147, (b) 667, (c) 417, (d) 123, whereas in 1938 the corresponding deaths were (a) 595, (b) 319, (c) 175, (d) 45. This means that from these forms of tuberculosis the death rate per million living fell from 88 in 1921 to 25 in 1938, a reduction of 72%. The fall in the death rate from all other forms of tuberculosis during the same period was from 1,037 to 607 per million living, a reduction of 42%.

It is also generally agreed that most cases of (e) tuberculosis of the respiratory system and (f) tuberculosis of the central nervous system are the result of successful infection from human sources. Deaths from these forms of tuberculosis in 1921 were, respectively, (e) 33,505 and (f) 3,365, whereas in 1938 the corresponding deaths were (e) 21,930 and (f) 1,744. This means that from these forms of tuberculosis the death rate per million living fell from 973 in 1921 to 574 in 1938, a reduction of 42%.

These figures prove that the greatest percentage reduction (72% in eighteen years) has been in the mortality from those forms of tuberculosis most associated with infection from milk. In the absence of compulsory pasteurization this implies either:

(1) a great reduction in the amount of tuberculous milk sold to the public, or (2) a great increase in human resistance against bovine tuberculosis. It would be interesting to know to what extent pasteurization has been voluntarily adopted throughout England and Wales; and also whether there is any positive correlation between pasteurization and the incidence of those forms of tuberculosis associated with tuberculous milk.—I am, etc.,

London, W.8.

HALLIDAY SUTHERLAND.

Refresher Courses for Service M.O.s

SIR.—I have read with interest and entire agreement the very pertinent letter from Fl. Lieut. E. L. Graff (July 3, p. 19). I have been serving in the Navy since early 1941, and for the last year and a half have been in an aircraft-carrier. The whole question of "picking up the threads" of civilian medicine after the war has been in my mind for some time, and I am sure that thousands of G.P.s such as ourselves have been similarly exercised about it. Incidentally I assume that Fl. Lieut. Graff writes from the viewpoint of a general practitioner. Only a few weeks ago in a letter to my partner in London I commented on this very question, and urged him to try and get the matter taken up.

Service medicine, especially connected with flying, has many very interesting aspects, and here I imagine I have a fair amount in common with Fl. Lieut. Graff, but this is hardly likely to be of much value to the G.P. who hopes to return to civilian practice after the war, unless it be that he is able to appreciate a little more some of the strains and stresses—not all of them physical—to which mankind is subjected.

It is discouraging but inevitable that any case of illness likely to be prolonged cannot be kept in the sick-bay but has to be sent ashore as soon as convenient. This somewhat literal "clearing the decks for action" probably applies to a fighting ship at sea in wartime even more than to land-based units. Thus so much of one's medical care and treatment depends not upon clinical findings but upon what the ship is likely to do in the immediate future. It is only possible, of course, for a relatively small proportion of medical officers in any of the Services to serve in hospital ships or hospitals, and even this closer contact with medicine and surgery obviously cannot embrace a large number of the things one used to encounter in civilian practice.

This letter is not intended as a complaint, because the situation cannot be avoided, but it is an endorsement of one solution of a very important problem which will present itself as soon as the war is over. I venture to suggest that most of us when finally demobilized will be immediately required for the needs of civilian practice, not least that of relieving hardworking colleagues and partners who have held the fort in our absence. In fairness to all let us do this as efficiently as possible. May it not be said in after-years that the immediate post-war period of world war No. 2 showed a decline in the standard of civilian medical service through lack of a little not too difficult forethought and planning.—I am, etc.,

W. B. MUMFORD, M.R.C.S., L.R.C.P.

Medical Boarding for the Merchant Navy

SIR.—When Dr. S. H. Waddy's letter appeared in your issue of Aug. 21 (p. 248) it was not the intention of the Shipping Federation to make any comment. It was felt that he was no doubt recording his honest opinion, but that thinking people would realize that the sweeping generalizations which he made, apparently as a result of one voyage in a British ship, were hardly likely to present a true picture. If the physical standards were as low as he suggested and so many men had to be paid off immediately before sailing through real or pretended disabilities, hardly a ship would get to sea without extraordinary delay. The Ministry of War Transport and those who are responsible for managing our ships know that this does not occur. Moreover, "physically miserable specimens" could hardly have endured 4 years of strain, always in the front line, with the added trials of voyages to North Russia in mid-winter, days in open boats, and long periods in West African ports. As, however, two further letters have now appeared in your issue of Sept. 11 (p. 340), in one of which the Shipping Federation is specifically mentioned, it seems necessary to make one or two brief comments.

Dr. G. D. Gray says that the Shipping Federation has shirked its responsibilities in the matter of medical organization. What seems to be forgotten so often is that the Merchant Navy is an industry and its members are civilians. So far as I am aware no civilians can be compelled to undergo any special form of treatment, or remain in a particular hospital for observation, or submit to vaccination and inoculation. Dr. Gray goes on to say that men suffering from such disabilities as fits, diabetes, tuberculosis of the lung, hernia, duodenal ulcer, and venereal disease can put to sea as easily as Grade I men. This statement cannot be accepted for one moment. The medical officers appointed to examine seamen before each voyage are responsible and qualified men, and further comment seems unnecessary.

Although Dr. Alec Wingfield opens up a wide subject in his very reasonable letter, there is only one statement which should be corrected at once. He suggests that it is within the arbitrary power of one Federation medical officer to deprive a man for ever of his livelihood. Even in peacetime the fact that a man was turned down by a Federation medical officer before a particular voyage did not debar him from the sea for ever. In wartime, now that there is an Essential Work Order covering seamen, a man who is declared unfit by a Merchant Navy Reserve Pool medical officer cannot be discharged from the sea service unless the medical opinion is supported by that of a medical referee appointed by the Ministry of War Transport; and even after the medical referee's opinion has been given the seaman has the right of appeal.

The above comments are only intended to correct mis-statements, and no attempt is made to deal with all the questions that have been raised. The industry and the Government are fully alive to the problems which must be faced if the health of seamen—as of all industrial workers—is to be maintained and improved, but it is impossible to discuss them fully and impartially through the medium of correspondence columns.—I am, etc.,

Ealing, W.5.

H. W. GREANY,
Secretary, the Shipping Federation.

Stilboestrol for Prostatic Enlargement

SIR,—It would indeed be unfortunate if the letter from Dr. McGee in your issue of Sept. 25 (p. 403) were allowed to influence the use of stilboestrol in the treatment of carcinoma of the prostate. We are not aware of any scientific observations on the treatment of benign enlargement of the prostate with oestrogens, but we have had considerable experience of the treatment of carcinoma of the prostate by means of these agents. There exists an extensive literature, mainly from American sources, on the rationale of this treatment. Dr. McGee can find an excellent summary of this in A. Haddow's able article in the symposium of the Faculty of Radiologists (1943, discussion, pp. 16, 31).

We ourselves have observed eight cases of carcinoma of the prostate which have been rendered completely symptom-free by stilboestrol treatment. From private information we are informed that some American cases are still completely controlled after 4 years of treatment. In our experience side-effects are slight, and often entirely absent. Even in their worst form, however, when contrasted with the sufferings associated with carcinoma of the prostate, they pale into insignificance. It would be most regrettable if sufferers from this fatal condition were to be prevented from obtaining the relief that stilboestrol can give on account of Dr. McGee's letter.—We are, etc.,

E. C. DODDS.
KENNETH WALKER.

Childhood Infection and Adolescent and Adult Phthisis

SIR,—To quote from Dr. A. N. Robertson's letter (Sept. 18, p. 373)—“that according to the hypothesis in Report V these symptomless adolescents are the very people who eventually will develop manifest disease, and that in the majority of these cases the expected spread of the disease comes sooner or later after a variable interval.” This purports to represent Dr. Macpherson's view in Report V of her article in the *Journal* of July 24 (p. 98). Dr. Macpherson has made it clear that the

cases referred to are symptomless, but with radiological evidence of active disease. This is clearly stated in paragraph 5 of Report V of her article. I entirely agree with Dr. Macpherson that artificial pneumothorax is the correct form of treatment for these cases. Once it has been decided that the disease is active there is no point in waiting until symptoms develop. I find it difficult to understand those tuberculosis physicians who wait for T.B.-negative cases to become positive cases before attempting artificial pneumothorax. I would suggest to Dr. Macpherson that all artificial pneumothorax cases should be kept under supervision in a sanatorium for six months as a precaution against complications, which are more liable to occur during the first part of the treatment and which can be dealt with effectively in a sanatorium.—I am, etc.,

Chesterfield.

H. P. FERNANDES.

Future Health Services

SIR,—It is to be hoped that every member of the profession has read Dr. Anderson's masterly address (*Supplement*, Sept. 4). Not everyone will agree with all the opinions expressed, but few could desire a more level, realistic, and orderly appraisal of the present situation. It is curious how rarely medical men appear to retain the sincere scientific approach apart from their actual dealings with patients. If Dr. Gaskell's estimate is correct (Sept. 11, p. 342), 95% of his colleagues simply refuse to recognize the history, signs, and symptoms of the body politic. Or can he possibly mean that these “non-politico-aquiescents” are contemplating a *coup d'état*? In which case they would do well to ponder the advice given in Dr. Anderson's last paragraph under the heading “100% v. 90%.”

I agree with Dr. Gaskell that remuneration under the Factory and N.H.I. Acts is very low, but I do not think that “this is a sample of Governmental valuation of our professional services.” In my view it represents the valuation we have set upon ourselves by lack of corporate idealism and the debasement of our members to the level of competitive business units. And being “equipped neither psychologically nor occupationally for mass combination and resistance” we can hardly be surprised at the general tone and outcome of our dealings. Yet if it were so minded the profession has the opportunity to establish for itself a position of independence and dignity comparable with that of His Majesty's judges. I cannot agree that a vocation free to direct its united effort in the cause of science and humanity would lack a sufficiency of the right type of entrants if it were easily accessible to the right type of man. It is true that “a different type of person would begin to enter it,” and it is not surprising that many present members of the profession consider that it would be unsuited to them. But it does not follow that “the entire status of the profession would infallibly be lowered.”

Dr. Gaskell is mistaken in saying that I deprecated delay pending demobilization.—I am, etc.,

Eye, Suffolk.

J. SHACKLETON BAILEY.

British Schools and Austrian Doctors

SIR,—It should be recorded in the history of the Vienna School (discussed in your issue of Aug. 21, p. 240) that after the invasion of Austria by Hitler the British medical schools gave studying facilities to fifty Austrian doctors. To many of them, who were deprived of all means by the Nazis, free study for two years has been granted by the British teaching hospitals. With the permission of the British Government and the aid of the B.M.A. opportunity to qualify under special conditions was given to assistants and students of men whose names are still well known in the medical profession of this country. Böhler, Eiselsberg, Freud, Holzknecht, Marburg, Neumann, Pirquet, Wagner-Tauregg, Wenckebach, Wertheim, and others attracted many British doctors. These and other British medical men, for reasons of humanity and as a protest against Nazi oppression, organized a hospitality in an unprecedented way in the history of medicine. The sympathy for Vienna's music and Austria's mountains might have endorsed their decision.—I am, etc.,

Royal National Orthopaedic Hospital,
Stanmore.

F. FREUND.

Obituary

SURG. REAR-ADML. SIR WILLIAM WHEELER

We are indebted to Prof. T. GILLMAN MOORHEAD for the following appreciation:

It is not easy to write with detachment concerning one who has been a close and intimate friend for more than forty years. Wheeler entered the Medical School of Trinity College in 1896 along with the present writer and some fifty others. From the outset he took a keen interest and played an important part in many college activities, including the Dublin University Biological Association. Of this association he soon became a member of council, later secretary, and finally, as a comparatively young graduate, was elected president. His presidential address on the occasion of his opening meeting dealt with the novel subject of the plating of fractures, and among the speakers on his platform was Sir William Arbuthnot Lane, who was then approaching the zenith of his surgical fame.

As a student Wheeler sustained a serious accident which at one time looked like proving a calamity. Walking with friends one evening in St. Stephen's Green, the party broke up, some electing to return home. After a moment's hesitation Wheeler decided to join the home-going group, and, turning, ran to join them. The night was very dark and he collided with an iron railing which protected a tree in the pathway. The railing had projecting spikes situated at a dangerous level; one of these penetrated his eye, inflicting a serious wound. Immediate removal of the damaged eye was recommended, but Wheeler naturally hesitated. A few days later, however, signs of irritation in the other eye developed and so immediate enucleation became imperative. On recovery Wheeler was advised to claim compensation from the Board of Works for their negligence; the Dublin Corporation resisted the claim, and litigation followed. Various novel legal points were involved and the case dragged on from court to court. At last the Board, realizing that judgment was likely to be given against them, offered a settlement out of court; this was accepted and Wheeler was free to resume his interrupted studies. He was determined to adopt surgery as his profession and in no way to permit the misfortune he had suffered to handicap or interfere with his work. Shortly afterwards he gained an appointment on the staff of Mercer's Hospital, and so began his brilliant surgical career. Of that career and of his contributions to surgery I do not attempt to write. It was after his graduation that he and I joined together as teachers of surgery and medicine respectively, and the association then begun continued for the rest of his life. Only a few days before his death I received a letter from him telling me of an impending visit to Dublin and of his joy in coming back for a few days to a country that he loved so well. He always felt happy in Dublin. In London, where he had settled some years before the war, he never felt quite at home. He missed the easy *camaraderie* of Irish life, where friends and acquaintances constantly drop in for a casual meal, a chat, or merely to pass the time of day.

As a surgeon and as a man of affairs Wheeler early showed much independence of mind and great courage in stating and defending his opinions. As a companion he was always entertaining; no company was dull which included him as a member. Often gay and light-hearted, he possessed a puckish humour resembling that of George Bernard Shaw, with whom he was proud to claim kinship. With great charm of manner and a vivid personality, he was a good talker and a sympathetic listener. He was no respecter of persons, was unconventional, and, not infrequently, controversial. When occasion demanded he could be serious. On committees he was shrewd and adroit, an excellent chairman, and full of resource. If in private life one consulted him on any matter of difficulty he would always listen patiently, and his advice was almost invariably wise. One felt he had great knowledge of the world, was prudent and far-sighted. As a surgeon, as I knew him, Wheeler was a brilliant operator. A great believer in travel and in seeing personally the work of other surgeons, he early recognized the value of team work. Soon after qualification he paid a visit to Kocher of Berne and renewed his visit for several years. During those visits in the afternoons we had many a pleasant bathe in the river and walks and talks on the terrace. Later he made a point of visiting all the important centres in England: Sir Robert Jones in Liverpool, Moynihan in Leeds, and, in more recent years, Wilkie in Edinburgh and many others. He was an intimate friend of both Willie and Charlie Mayo, and paid several visits to Rochester. He also visited Crile in Cleveland and other American and Canadian centres. Many will remember the speech he made when, as President of the Royal College of Surgeons in Ireland, he entertained the Mayos, who had that day been admitted to the Honorary Fellowship. As a teacher he was most attractive; his classes at Mercer's Hospital were always thronged. Up-to-date and incisive, he did not hesitate to condemn methods and practices of which he did not approve or

which he had found faulty. His many communications to surgical journals had the same quality of incisiveness and lucidity of diction, and displayed strongly held opinions.

When on holiday he loved the country though quickly became impatient to return to work. He was a good shot and a keen fisherman. On one occasion he killed six salmon between dinner and bedtime on a summer evening. He looked forward when the war was over to returning to Ireland, where he intended to write his reminiscences; already, indeed, he had collected much material for the purpose. The annals of medical biography will be the poorer for the lack of a volume which would undoubtedly have been an alive and lively record of many and varied experiences.

Surg. Rear-Adml. G. GORDON-TAYLOR writes:

Sir William Wheeler lived an eager life of unremitting activity. He had practised in two capitals—his own native Dublin and London; he served in two wars; he held high rank in each conflict in a different branch of the Forces; death came to him suddenly when he was one of the Consulting Surgeons to the Royal Navy. He came of a famous surgical stock, for his father, like himself, was President of the Royal College of Surgeons in Ireland, and almost from his own cradle he had been in personal contact with such surgical giants as Butcher and Stokes of Dublin. Wheeler was always immensely proud of the medical and surgical tradition of the Irish capital and of the hospitals where he received his early training and where the major portion of his surgical life was spent. He adhered with staunch devotion to those methods of surgical technique in which he had been schooled or which he had embraced as a postgraduate disciple in clinics in Britain, America, or Europe; he admired Moynihan, worshipped Kocher, and adored Robert Jones. Yet he was no mere *laudator temporis acti*, despite his hero-worship and his rich knowledge of surgical, and especially Irish surgical, history. Though intensely loyal to the Thomas splint, he was not blind to the value of plaster-of-Paris; he was not merely a suprapubic prostatectomist, but also a master of endoscopic resection; the first occasion on which I saw de Martel's intestinal clamp used was in Mercer's Hospital about 1923.

Till the end of his life Wheeler retained that feeling "which impels a teacher to be a contributor and to add to the stores from which he so freely draws." His surgical interests and writings were catholic in their scope. The list of his contributions bewilders by reason of the number and diversity of subject, and the reader is enthralled by the manner of presentation and captivated by the impeccable language in which each communication is couched. Wheeler had a very special interest in the injuries and diseases of bone—indeed, he was president of the Orthopaedic Section of the British Medical Association in 1933, and served for many years on the Medical Advisory Council on Artificial Limbs, Ministry of Pensions. He was an intransigent opponent of all who dared to decry Syme's amputation, and hostile criticism of the operation only made him champion the procedure more ardently.

ALES HRDLICKA, M.D., D.Sc.

Dr. Ales Hrdlicka, the world-famous anthropologist, who died in Washington on Sept. 5 at the age of 74, was Czech by birth. He was born at Humpolec, Bohemia, on March 29, 1869. After studying in his native town he emigrated with his parents in 1882 to New York, where he studied medicine, graduating M.D. in 1892. He then proceeded to Paris, where he graduated in 1894, returning to join the N.Y. State service as research alienist, becoming later an associate in anthropology at the State Pathological Institute. In 1899 he took charge of the section of physical anthropology of the Hyde expedition to Mexico and South-Western United States, financed by the American Museum of Natural History of New York. In 1903 he became associated with the U.S. National Museum in Washington, an association that was to last 39 years, during which he made that museum the greatest in the world. With his more erudite and senior colleague Dr. Franz Boas, who died at the end of 1942, he made the American contribution to anthropology highly respected in Government and scientific circles throughout the world. In 1918 he founded the *American Journal of Physical Anthropology*. His name, already a household word, became linked with the theories that the Amerind is of Asiatic origin, that the original home of *Homo sapiens* was European and not, as usually held, Asiatic, and that Neanderthal man was not a species of *Homo sapiens* but represented a phase in his evolution. Perhaps in no other departments of science than the twin ones of archaeology and anthropology are theories just mere working hypotheses to be discarded whenever newer facts emerge. Hrdlicka's conclusion that Neanderthal blood persisted in late Palaeolithic time as a result of direct evolution of Neanderthal man into *Homo sapiens* is by no means acceptable to other workers. Against

his denial of the Asiatic origin of *Homo sapiens* and his affirmation of his European origin may be mentioned the fact that the Rhodesian and Boskop skulls from Africa, the Wadjak and Solo ones from Java, as well as the Talgai skull from Australia, are Pleistocene specimens at least contemporaneous with, if not ancestral to, the Aurignacian in Europe. He was elected an Hon. Fellow of the Royal Anthropological Institute in 1918, and awarded the Huxley Medal in 1927. A powerful and prolific writer, his loss to science and to medicine, which he never abandoned throughout his life, is a heavy blow.

R. E. G. A.

H. G. BAYNES, M.B., B.Ch.

Dr. H. G. Baynes, who died on Sept. 6, came into the foreground of medical psychology in England as interpreter of the views of C. G. Jung, whose confidential assistant he was at Zurich for three years after the last war, and he organized and took part in Dr. Jung's expedition to East Africa in 1925-6 for purposes of psychological research among the Masai tribes of Mount Elgon, Kenya. The neglect of Jung's views compared with those of Freud and Adler in this country has been partly due to paucity of exponents. After the death of Dr. Constance Long Dr. Baynes was almost alone in the field.

Born at Hampstead on June 26, 1882, Helton Godwin Baynes was educated at Reading, at Trinity College, Cambridge, and at St. Bartholomew's Hospital. At Cambridge he played football for his college and swam for the University, but he became best known as a fine oarsman. A man of exceptional physique, he was in the Cambridge boat which beat Harvard in 1906, and rowed five in the Cambridge crew which beat Oxford in 1907. At Bart's, after qualifying in 1910, he served as house-physician. He was surgeon-in-charge of the Red Crescent Mission to Turkey during the Balkan War of 1911-12, and then worked as a general practitioner at Wisbech for two years; he left that in 1915 to serve in France, Mesopotamia, and Persia with a temporary commission in the R.A.M.C. Before going to Zurich he was for a short time on the resident staff of the Maudsley Hospital, and he returned to England for a year to work as consulting neurologist under the Ministry of Pensions. Thenceforward Godwin Baynes devoted himself to analytical psychology, and published many papers and books on this and kindred subjects. He was the translator and editor of Jung's *Psychological Types* and two other of Jung's works. An early indication of his bent had been given in Baynes's Cambridge M.B. thesis (1912) on "Fear as the Principal Causative Factor in Hysteria." While at Zurich in 1921 he contributed a paper on psycho-analysis and the psychoses to the *Journal of Mental Science*, and three years later wrote on primitive mentality and the unconscious for the *British Journal of Medical Psychology*. In 1939 he published a book *Mythology of the Soul*, being a research into the unconscious from schizophrenic dreams and drawings, in which he elaborated a technique for exploring the unconscious, and gave a full-length study of the schizophrenic make-up. It was reviewed at some length in these columns by Sir Walter Langdon-Brown on May 18, 1940. Baynes's last published book was *Germany Possessed* (1941).

Dr. MARTIN HALLAM died at his home, Leas Lodge, Yalding, Kent, on Aug. 18. He came of a medical family, and was educated at Repton School, the London Hospital, and Sheffield University. After qualifying M.R.C.S., L.R.C.P. in 1909 he held resident posts at the Royal Hants Hospital, Leicester Royal Infirmary, Wolverhampton General Hospital, and the Jessop Hospital, Sheffield. He served in the R.A.M.C. 1914-18 and afterwards began practice at Yalding. He had a keen interest in clinical medicine and availed himself of postgraduate instruction whenever opportunity permitted. He was anaesthetist to the Kent County Ophthalmic Hospital for a number of years. His pleasure was country life, and from his early youth he had a never-failing fondness for birds, trees, and flowers. He is survived by his wife, his son—Squadron Leader Ian Hallam, who is a prisoner of war in Germany—and daughter. Dr. Hallam kept the Maidstone Division going for a long time and worked hard for the B.M.A. In the words of an old colleague, "he was a very good man."

Lt.-Col. Felix Smith, R.A.M.C. writes: Many hundreds of doctors in the R.A.M.C. who have done a tour of duty in West Africa came to know Dr. E. C. SMITH, and will learn of his death with great sorrow. Those of us who disembarked at Lagos received from him a short course of instruction which

converted us all into enthusiasts for the subject of tropical diseases, so great were his knowledge and his gift for teaching. Even more shall we remember the visits, half professional and half social, to his laboratories at Yaba. For several hours he kept us entranced, passing through the extensive laboratories, libraries, and experimental animal houses. There was no showmanship in Smith's teaching; it was clear, concise, and modest, and one realized that this was a man who not only knew but had to a large extent created his subject. In his charming bungalow, where he would entertain his little group of students, he had created an atmosphere of the very best type of home, and those visits remain in our memories as one of the oases in the course of the war. We in the R.A.M.C. mourn the loss of a man of great intellectual attainments and great gentleness of spirit.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Many of the professorial chairs in the University have become vacant during the war and the elections to most of them have been held in suspense by the Council of the Senate. In six cases the suspension has been terminated by Grace of the Senate, and among those elected to the vacant chairs are Dr. A. C. Chibnall, F.R.S., to the Sir William Dunn Professorship of Biochemistry; Dr. R. A. Fisher, F.R.S., to the Arthur Balfour Professorship of Genetics; and Dr. David Keilin, F.R.S., to the Quick Professorship of Biology (re-elected).

At a Congregation held on July 31 the following medical degrees were conferred:

M.D.—L. J. Bendit, J. Yudkin, and R. Wylie-Smith.
M.B., B.Chir.—J. Attenborough, E. H. Back, R. A. J. Baily, H. W. Balme, D. R. Barnes, C. H. Barnett, R. F. Bates, D. L. Bridgewater, R. A. P. Brown, W. L. Calnan, D. J. Conway, R. A. D. Crawford, J. Davenport, M. B. Devas, D. H. Drennan, R. M. Forrester, H. A. Fraser, M. R. Geake, R. N. R. Grant, H. C. Gupta, B. Haigh, E. H. Hare, H. Harris, J. K. Hinds, G. Hildick-Smith, P. H. Huggill, P. F. Jones, J. O. Laws, J. Lister, J. C. Lloyd, R. E. Loder, C. S. McKendrick, D. H. Makinson, N. M. Mann, P. G. Mann, A. S. Mason, R. G. May, P. H. Mitchell, P. A. G. Monro, T. Norman, J. E. Oliver, W. J. L. Pain, J. McE. Potter, J. R. Robinson, K. C. Robinson, P. H. Rogers, P. H. Schurr, O. L. S. Scott, E. L. Simons, P. S. Smith, I. S. Staddon, T. R. Steen, R. V. Stone, J. D. Trethowan, L. R. Twentymann, G. S. Udall, D. Vétel, D. B. Beckwith Whitehouse, E. H. Williams, O. H. Wolff, W. D. Wylie.
* By proxy.

During the months of July and August titles of the degrees of M.B., B.Chir. were conferred by diploma on J. Hardy and Mrs. A. B. Wilcock, both of Girtton College.

UNIVERSITY OF LEEDS

The inaugural lecture of the Faculty of Medicine will be given by Sir John Graham Kerr, F.R.S., M.P., emeritus professor of zoology in the University of Glasgow, in the Riley-Smith Hall of the University Union, on Wednesday, Oct. 20, at 3.30 p.m. Subject: "Medicine and Education."

The following have been successful at recent examinations:

M.D.—A. J. E. Barlow, D. M. Davies.
FINAL M.B., B.Ch. (Part II).—Marjorie Aldred, Elizabeth C. Armstrong, H. J. Balsham, Ruth Blackwood, T. P. Burton, H. S. Capcore, Winifred M. Davies, J. Dawson, Sybil D. Dawson, J. R. Edge, R. H. Foxton, R. P. Goulden, J. S. Groves, R. Harris, G. Harrison, M. Hutchinson, A. R. Hyslop, G. I. Isaacs, A. Jervis, J. R. Kirby, Joyce M. Longley, W. Marshall, H. B. Milner, S. N. Nathan, Marjorie M. Neil, Dorothy C. Newell, F. M. Parsons, D. I. Peacock, Elcanor R. Raistrick, J. Ruston, M. Silverman, M. H. C. Stone, D. R. K. Street, Margaret A. Sufferm, M. N. Tempest, J. S. Thorburn, D. Weiner, W. Whitaker, R. C. Woodcock.†

* With second-class honours. † Distinction in therapeutics.

The following awards have been made: West Riding Panel Doctors' Prize and William Hey Medal—O. Magidson. Edward Ward Memorial Prize in Surgical Anatomy and McGill Prize in Clinical Surgery—G. Harrison. Hardwick Prize in Clinical Medicine—W. Whitaker. Scattergood Prize in Obstetrics and Gynaecology—Divided between D. Weiner and W. Whitaker.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The Moynihan Lecture will be delivered at the College, Lincoln's Inn Fields, W.C., by Air-Cdre. P. C. Livingston, O.B.E., A.F.C., on *Visual Problems of Aerial Warfare*. Part I—Night: Studies in the Dark-adapted Eye, on Tuesday, Oct. 5, at 4 p.m.; and Part II—Day: The Influence of Flying Conditions upon Vision, on Wednesday, Oct. 6, at 4 p.m. Fellows and members of the College are invited to attend. Students and others who are not Fellows or Members of the College will be admitted on presenting their private visiting cards.

The following lectures by members of the scientific staff of the Imperial Cancer Research Fund will be delivered at the College, at 3.30 p.m., Thursdays, Oct. 7 and 14 respectively. Mr. H. G. Crabtree: Metabolic Disturbances and the Cancer Problem. Prof. W. E. Gye, M.D., F.R.S.: The Problem of Chemotherapy in Cancer. The lectures are open to medical practitioners, scientists, and advanced students.

The Services

The following have been mentioned in recognition of gallant and distinguished services in North Africa: Major-Gen. (acting) E. M. Cowell, C.B., C.B.E., D.S.O., T.D., late R.A.M.C.; Col. W. D. Arthur, M.B.E., late R.A.M.C.; Col. (temp.) J. R. N. Warburton, M.C., and T. Young, R.A.M.C.; Major (temp. Lieut.-Col.) J. C. Barnetson, R.A.M.C.; Capt. (temp. Major) E. G. Houghton and W. Ironside, R.A.M.C.; Capt. (acting Major) J. W. Totten and Capt. D. Collins, E. O. Low, and M. Young, R.A.M.C.

The following appointments, awards, and mentions have been announced in a *Supplement to the London Gazette* in recognition of gallant and distinguished services in North Africa:

O.B.E. (Military Division).—Col. (acting) W. E. Underwood, Col. (temp.) C. H. K. Smith, M.C.; Lieut.-Col. (Brevet Col.) G. W. R. Bishop, T.D.; Majors (temp. Lieut.-Cols.) J. H. J. Crosse, P. T. L. Day, A. S. Hollins, R. G. M. Keeling, M. MacEwan, D.F.C., T.D., J. J. O'Connell, and J. Trotter, R.A.M.C.; Capt. (temp. Major) W. A. Law, H. W. Rodgers, A. R. Clarke, and W. C. Gledhill; Capt. C. J. Cobbe, R.A.M.C.

D.S.O.—Col. (temp.) A. L. Crookford, M.C., T.D., R.A.M.C. Bar to M.C.—Capt. R. R. Gordon, M.C., R.A.M.C.

M.C.—Capt. G. S. Hodge, G. D. Park, and D. Wright, R.A.M.C. Mentioned in *Dispatches*.—Brig. (temp.) E. W. Wade, D.S.O., O.B.E., late R.A.M.C.; Brig. (temp.) H. L. Garson, O.B.E., M.C., T.D.; Col. (temp.) J. H. Donnelly, T.D., T. B. H. Tabuteau, and M. J. Whelton; Col. (acting) P. F. Palmer; Lieut.-Col. R. Coyte; Majors (temp. Lieut.-Cols.) G. Anderton, A. Angus, T.D., J. J. M. Brown, E. A. Downes, R. W. Fairbrother, J. C. Gilroy, W. Graham, N. G. Hill, M.C., T.D., H. H. Kenshole, F. P. L. Lander, F. R. Langmaid, J. D. P. Macpherson, W. R. Martine, M.B.E., T.D., J. W. Orr, M.C., A. S. Pern, T.D., J. K. Slater, K. S. Smith, J. G. E. Vachell, D. S. P. Wilson, A. J. Pitkeathley, and R. V. Phillipson; Major H. W. L. Nichols; Capt. (temp. Major) S. S. Chesser, D. S. Cowrie, W. H. Gabb, E. H. C. Harper, B. Holden, J. R. Kingston, W. R. Merrington, L. O. Mountford, W. L. Ogle, C. L. Owen, J. B. Pirie, and E. C. Zorab; Capt. T. P. Blanshard, J. Braham, J. G. Cassidy, J. P. M. Donnelly, C. D. Farris, C. C. Fenwick, R. A. Hooper, N. A. Jevons, D. G. Liversedge, H. M. MacFie, M.C., J. McKerrigan, J. M. McKiddie, M. D. Milne, O. D. Morris, D. F. O'Neill, A. Paterson, A. Percival, W. R. Perry, L. J. Samuels, D. G. Sheffield, A. W. Sloan, M. G. Sutton, E. R. Winkelman, and A. B. White, R.A.M.C.; Lieut. W. H. G. M. Ling, C. W. Richards, and T. Williamson, M.C., R.A.M.C.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the rising trend of scarlet fever and diphtheria continued, with increases of 226 and 75 respectively. Notifications of whooping-cough were down by 177, of measles by 158, and of dysentery by 37.

The higher incidence of scarlet fever was general throughout the country: in Yorks West Riding notifications were up by 45. A small upward trend in diphtheria has occurred for four consecutive weeks, and the disease is at the highest level since May.

Notifications of dysentery still continue to be high, although there are 37 fewer cases than in the preceding week. The most important of the new outbreaks was in Bedfordshire 29 (Bedford M.B. 21, Luton M.B. 8). Other centres of infection were Kent 29 (Rochester M.B. 20); Hertfordshire 23 (Watford M.B. 20); Buckinghamshire 21 (Wycombe R.D. 12, Aylesbury R.D. 9). The three counties of Leicestershire, Gloucestershire, and Yorks West Riding had 18 cases, compared with a total of 99 in the preceding week.

In *Scotland* there was an outbreak of measles, 58 cases, in Lanark County. Dysentery fell by 24, but was still at a high level, the decrease being due to the North-Eastern area, where the cases dropped from 53 to 18. The largest returns were in Dunbarton County 39, and in Glasgow 15. In the House of Commons on Sept. 21 Mr. Westwood told Mr. McNeill that from Jan. 1 to Sept. 11, 1943, 5,245 cases of pulmonary tuberculosis and 2,204 of non-pulmonary tuberculosis were notified in Scotland.

In *Eire* the returns of infant diarrhoea and enteritis were affected by the inclusion of 46 cases which occurred in a Dublin hospital during the preceding month.

The Week Ending September 18

The returns of infectious diseases in *England and Wales* during the week included: scarlet fever 2,639, whooping-cough 1,531, diphtheria 723, measles 491, acute pneumonia 365, cerebrospinal fever 44, dysentery 268, paratyphoid 8, typhoid 7.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (including London), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical Notes in Parliament

Recruitment and Allocation of Doctors

On Sept. 21 Sir E. GRAHAM-LITTLE asked the Minister of Health what body was now responsible for the allocation of doctors for civilian services and the fighting Services respectively; what was the relationship between the Central Medical War Committee and the British Medical Association; and how far this committee was subordinate to the Shakespeare Committee in respect of the allocation of medical man-power. Mr. BROWN replied that the Medical Personnel (Priority) Committee, of which Sir Geoffrey Shakespeare was chairman, was responsible for advising, within the limits of any direction that might be given to it by the Government, on the number of doctors to be allocated to the civilian and fighting Services and on matters incidental thereto. The Central Medical War Committee was related to the British Medical Association only to the extent that its secretariat and offices were provided by the Association and that about two-thirds of its members were office-holders or nominees of the Association. The Central Medical War Committee, among other functions, advised on the selection of individual doctors for allocation to the various Services, and was not subordinate to the Shakespeare Committee except in the sense that it must conform with the recommendations of the latter committee as adopted by the Government.

Housing and Health

On Sept. 21 Miss HORSBRUGH informed Mr. Craven-Ellis that the Minister of Health was not aware of statistics giving a direct quantitative relation between housing conditions and infectious disease, but crowding must naturally tend to favour the spread of such disease. Increased density of population involved generally both a higher incidence of infectious disease and an earlier average age of attack.

Medical News

To-day, Friday, Oct. 1, at 3 p.m., Miss Margery Fry, M.A., will give the inaugural address at the London (Royal Free Hospital) School of Medicine for Women, in the Medical School, 8, Hunter Street, Brunswick Square, W.C.

The opening of the 101st session of the College of the Pharmaceutical Society of Great Britain and the presentation of prizes will take place on Wednesday, Oct. 6, at 3 o'clock, at 17, Bloomsbury Square. The inaugural sessional address will be given by Mr. William Spencer Howells, president of the society.

A Radiotherapy Section meeting of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Oct. 16, at 10 a.m., when there will be a discussion on "The Treatment of Carcinoma of the Lung."

Dr. Ethel Browell, medical officer in charge of a first-aid post, Civil Defence Casualty Service, Sunderland, has been commended for brave conduct in civil defence.

Only a few hospitals have made a second application for films for testing the amount of radiation received by x-ray workers (*Journal*, Nov. 28, 1942, p. 644). The Ministry of Health (Circular 2718A) reminds hospital authorities that these tests should be repeated at intervals of three months where the reports are satisfactory, and earlier in other cases.

Viscount Weir, chairman of the Glasgow engineering firm of G. and J. Weir, Ltd., has marked his jubilee with the firm by giving £10,000 to the fracture clinic of the Victoria Infirmary, Glasgow. Five years ago Lord Weir established the clinic with a gift of £7,000, and his latest contribution is intended to develop and extend the work of a service which has proved of the utmost value.

By an Order made under the Defence Regulations which comes into force on Sept. 20, all nurses and midwives (other than members of the Civil Nursing Reserve) aged 18 to 40 must in future obtain employment through a local office of the Ministry of Labour. Employers will not be able to engage a nurse or midwife except through an appointments office unless she possesses an exemption certificate. These certificates will be issued to hospitals and similar institutions in respect of appointments to grades equivalent to that of a ward sister or above.

The address of the Royal Institute of Public Health and Hygiene is 28, Portland Place, W., and not as stated in the announcement of the series of lectures on national health (Sept. 25, p. 409).

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR: *Attilology Westcent*, London; SECRETARY: *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Potassium in Allergy

Q.—In "Discovery" some time ago it was stated from an American source that chloride of potash is most effective in the treatment of hay-fever. Has any experience of this been recorded in this country?

A.—The use of potassium salts has been frequently recommended in allergic conditions such as urticaria, asthma, and hay-fever. The theory behind this recommendation is that in many respects the physiological action of potassium is similar to that of adrenaline. In practice it has proved disappointing. Although enthusiastic reports have at times received wide publicity in the public press and radio in America, most of those who have used potassium chloride critically would agree that it is of limited value in allergy; that it produces many side-reactions, some of them extremely uncomfortable; and that it is decidedly less effective than acetyl salicylic acid (in cases not sensitive to aspirin) or ephedrine plus phenobarbitone in the relief of symptoms. No recent experience in this country is available.

Hyperidrotic Axillae

Q.—How can excessive perspiration in the axillae be checked? The patient concerned is a healthy girl of 24; she perspires tremendously in the axillae—not elsewhere—soaking and ruining her clothing, despite the use of rubber shields, of various proprietary applications for checking perspiration, and despite extremely careful personal hygiene. She is very sensitive about this condition, and now tends to avoid social functions, dances, tennis functions, etc., and is consequently adopting a somewhat "anti-social" attitude. Further suggestions for the treatment of this condition will be much appreciated.

A.—Hyperidrosis of the axillae is often maintained by a nervous disposition and over-consciousness of the dysfunction, so that a mild sedative such as tinct. belladonnae, mx , in a bromide mixture is often of value, combined with reassurance that the condition will improve. Locally, one might try a saturated solution of alum, to which 1% of formalin may be added if the skin tolerates the substance. X-ray therapy in doses of 200 r (90 kV) may be given thrice at two-weekly intervals. This has a temporary effect which encourages the patient, and combined with other measures is well worth trying.

Examining the Sputum in Pneumonia

Q.—I was much interested in the report of a meeting of the Section of Medicine of the R.S.M. held on March 23, in which a discussion took place on atypical primary pneumonia. During the last two winters I saw a large number of cases which correspond closely both clinically and on radiological examination with those described at the meeting. Examination of the sputum of many of these patients by direct smear often revealed fairly large numbers of pneumococci, usually together with a small proportion of other organisms such as streptococci. I have never been quite clear as to how much reliance could be placed on the results of sputum examination in determining the cause of a pneumonia, and I should be grateful for information on this point.

A.—Claims are made from time to time for the diagnostic and prognostic value of the naked-eye appearances or microscopical examination of sputum in pneumonia, but apart from the classical and practically constant association of rusty sputum with lobar pneumonia, it is doubtful if these claims can be substantiated. Certainly little significance can be attached to the finding of Gram-positive diplococci in a stained smear of sputum, since *Str. viridans*, constantly present in the nasopharyngeal cavity, often appears in diplococcal form. The presence of numerous pus cells and oat-shaped diplococci with a negative halo is, however, suggestive of a pneumococcal infection. Demonstration of capsular swelling

(Neufeld quellung) after mixing the sputum with antisera of the different pneumococcal types is the only reliable method of identifying pneumococci by direct microscopical examination, and it is a pity that this technique has never become popular in this country. With it the identification of certain pneumococcal types—for example, I, II, V, and VII—in the sputum of a febrile patient will almost always mean lobar pneumonia. Other pneumococcal types may be present in the throat as saprophytes. Purulent sputum in which there are many small clumps of staphylococci or short, thick Gram-negative bacilli is suggestive of the rare staphylococcal or Friedländer pneumonias, but streptococci in the sputum have no particular significance because the mouth streptococci may occur in short chains.

Renal Calculi

Q.—Can an oxalate renal calculus be made friable and break up into small fragments by taking large doses of calcium chloride or herbs? To prevent recurrence, what are the items of diet to be avoided? Are tea, chocolate, lettuce, grapes, and eggs contra-indicated? Why is the excretion in urine of calcium oxalate excessive when free HCl is given by mouth, and also when there is an absence of free HCl from the gastric juice? Does vitamin B₁ affect renal calculi?

A.—An oxalate calculus is very difficult to break up since calcium oxalate is soluble only in relatively strong acid. If the calculus is a mixture of calcium oxalate and phosphate—the commonest form of oxalate stone—it may be possible to attain solution of the phosphate by acid treatment—such as with calcium chloride or acid-producing herbs—although even this is hindered by the presence of the colloidal material which binds the salts together in the stone. If, on the other hand, the calculus is a mixture of oxalate and urate, acid treatment would tend to cause deposition of urate. A rational method of treatment cannot be advised without a knowledge of the composition of the stone.

Items of diet containing considerable amounts of oxalate and which should be avoided are spinach, rhubarb, and strawberries. There are small amounts in cocoa, coffee, tea, and pepper. Lettuce, grapes, and eggs are oxalate-free.

Excessive excretion of oxalate when free HCl is given is due to increased absorption of the calcium oxalate in foods owing to the increased acidity. Alkaline treatment diminishes excretion of oxalate by hindering absorption of calcium oxalate from the food. In the absence of free HCl in the gastric juice, carbohydrate is liable to undergo fermentation, during which oxalic acid is formed. Thus in this condition excessive oxalate might be excreted even on an oxalate-free diet.

There is no evidence that vitamin B₁ affects renal calculi. (Calcium phosphate stones are favoured by a high-calcium low-vitamin-A dietary.)

Diet in Pregnancy

Q.—In the past various restrictions in the diet of pregnant women were recommended, often enough without much basis in reason. I should be glad to know whether, for the normal pregnant woman, any restrictions of diet are indicated at any stage of pregnancy, and whether, too, supplements of, for example, iron, calcium, and vitamins should be made to the diet, especially in the last two or three months of pregnancy.

A.—Restrictions of diet are unnecessary in normal pregnancy. During the last trimester of pregnancy nutritional strain is at its greatest. Provided she eats all her rations, varies and properly cooks her food, there is no need for the expectant mother to have supplements except cod-liver oil and orange juice. The present milk and cheese rations should suffice to cover her calcium needs. The administration of iron should be governed by the Hb level.

Distension of Bowel

Q.—I have two cases that present great difficulty in treatment. Both patients are women and they suffer from enormous distension of the bowel. The distension is not apparent, or at least not marked, in the mornings, but towards night the abdomen presents the appearance of a 7-months pregnancy, with, of course, a highly tympanitic note throughout. Constipation is not present and liq. paraff. produces a loose motion. What is the aetiology of this condition, and what treatment has any really good result? Neither is of a nervous temperament, but are hard at work in munition factories, while their husbands are in the Middle East.

A.—There appear to be three possible explanations of the cases: 1. Intestinal carbohydrate dyspepsia, in which the colon becomes distended by gas produced by fermentation of starch which has escaped digestion in the small intestine. Clinically this can be recognized by the relief of discomfort and disappearance of distension on passing flatus. The stools contain undigested starch granules and ferment on incubation. Relief follows avoidance of root vegetables and rice.

2. Interference with portal circulation. This is constant in cirrhosis of the liver and intermittent in obstruction caused by partial volvulus, which is often associated with megacolon. Relief follows

injection of 1/4 to 1 c.cm. pitressin, which completely evacuates the faeces and gas accumulated in the colon.

3. As the condition is described as intermittent and no mention is made of relief by passage of flatus, it is probably, like pseudo-cystitis, the result of abnormal descent of the diaphragm and not of intestinal distension. This may appear and disappear suddenly as a result of spasm of the diaphragm, which is generally hysterical in origin. But as in the two cases described the "distension" develops towards night in women who are hard at work all day, it may be the result of relaxation of the abdominal muscles caused by fatigue with consequent ptosis of the diaphragm. In this condition of pseudo-tympanitis x rays show no excess of gas in the colon, no excess of flatus is passed, and the base of the thorax is drawn in, in contrast with its expansion in ascites and when excess of gas is present in the colon. Relief follows instruction in diaphragmatic breathing, and in cases associated with fatigue the use of an abdominal support, or, preferably, rest in the recumbent position for half an hour after the midday meal.

Pest of Flies

Q.—What is the best way to deal with the fly pest?

A.—Fly sprays are difficult to obtain now because the pyrethrum supplies are all required by the Army. The following poison bait is a good alternative: 40% formalin, 15 parts; sugar, 15 parts; water, 70 parts. A tablespoonful is placed in several saucers every morning, and this will kill large numbers of flies. If the formalin is old, formic acid may be present, which should be neutralized with a pinch of sodium bicarbonate. Measures against adult flies are only palliative. It is essential to find the breeding site and, if possible, deal with that. Manure heaps, refuse, or other sources of decaying organic matter should be inspected for fly maggots. The local health department should be approached for measures to deal with these sites.

Bee Stings Again

Q.—I was called to a woman aged 42 who had been stung by bees the previous evening—in the scalp, left forearm, and right leg. All three areas were intensely swollen and painful; the patient was suffering from headache, malaise, and nausea. As the condition suggested an urticarial reaction, I injected 7 minims of a 1:1,000 solution of adrenaline subcutaneously. About a minute after the patient complained of faintness and became blanched; this was followed by a violent shivering and by a series of attacks in which the trunk became arched, as in tetanus, and there was bronchial and laryngeal spasm, causing difficulty in respiration. The pulse was full and bounding, and the patient retained consciousness, though she had difficulty in speaking. These attacks occurred at intervals of about five minutes for nearly three-quarters of an hour, then gradually decreased in violence and intensity and finally ceased, leaving the patient exhausted. There was a violent local reaction at the site of injection—a raised white wheal surrounded by a zone of redness. Why should adrenaline have such an unexpectedly violent effect? Can one be forewarned against such occurrences? And what is the best treatment? Is morphine or atropine indicated for relief of the spasm? The patient is a healthy woman at present having a course of weekly injections of oestrogen for relative sterility.

A.—This patient exhibits simultaneously symptoms resulting from two different causes: (a) Those characteristic of the allergic reaction to the bee stings: local swelling at the site of the stings; general symptoms—(1) mild and prodromal (headache, malaise, nausea); (2) allergic (bronchial and laryngeal spasm, difficulty in respiration, arching trunk—for by throwing the head well back breathing is facilitated). (b) Those characteristic of the pharmacological action of adrenaline: faintness, blanching, shivering, exhaustion. These normal pharmacological effects appear sooner and after smaller doses in some people than in others, and seem to be related to the patient's glycogen stores, as adrenaline converts stored glycogen into blood sugar, which is soon burnt up or excreted. Such effects can be mitigated by ensuring a good supply of glucose, and by keeping the patient recumbent. The "violent local reaction" described is probably the usual local blanching effect of adrenaline in an urticarial skin or during a dermatographic phase.

Where symptoms appear hours after the bite the treatment is: (a) To give a subcutaneous injection of 5 minims of 1 in 1,000 solution of adrenaline, and to leave the needle in position and give a further 2 minims each 5 to 15 minutes until no further general allergic symptoms are apparent, as the duration of the beneficial effect of an injection of adrenaline is very temporary. A 1 in 100 spray of adrenaline by mouth may be soothing if available. (b) To give ephedrine hydrochloride 1/2 gr., and repeat in three hours if any allergic symptoms remain. (c) To give plenty of glucose to combat unpleasant effects of the adrenaline, to which the addition of alcohol is not necessary whilst the pulse is "full and bounding." (d) To keep the patient lying down as long as possible.

The way to administer adrenaline with the least unpleasant effects is to give it in small repeated doses, the patient being recumbent, and an adequate glucose intake assured. Morphine is never indicated, and atropine only if the choking is due to mucous secretion rather than to oedema of the glottis.

LETTERS, NOTES, ETC.

Q.—Is there any reliable information about the value of medical diathermy in the treatment of diseases of the eye?

A.—Thermopile observations have shown that hot fomentations raise the local temperature of tissues very slightly, and this rise is confined to the superficial layers. There is no tangible increase of temperature in the anterior or posterior chambers of the eye or in the vitreous. Diathermy overcomes this limitation, and should be ideally effective in all inflammations of the eye. Clinically, diathermy has proved superior to fomentations in acute iritis and iridocyclitis, and possibly also in congestive secondary glaucoma, but the results have not been particularly striking.

Girl with Facial Hair

Q.—What is the best treatment for a moustache and beard in a young, healthy lady patient of 24 years?

A.—If there were any better way of removing hair from the face than shaving every man would use it, and there is no doubt it is the best way for women also if they can be persuaded to try it. Inferior alternatives are the removal of the hair by pulling it out with epilating wax. This is extremely painful on the upper lip. It produces a perfectly smooth face for some one to two weeks, but the hair has to be allowed to reach a certain length again before the wax can get a grip on it. Rubbing the face night and morning for a few seconds only with a piece of smooth pumice stone will often keep the hair short after it has been removed from the face in the first instance by shaving. Even without shaving, the regular application of pumice stone will eventually break the hair off and keep the face smooth, provided the growth is not too strong. Other alternatives are the application of depilatories, electrolysis, and diathermy. Depilatories such as are based on the alkaline sulphides keep the face smooth for rather longer than shaving, because they erode the hair for a short distance below the surface, but as they also erode the epidermis comparatively few people can use them on the face. Electrolysis and diathermy are only suitable for a comparatively small number of strong hairs. No form of radiation treatment can be considered safe for the permanent removal of hair from the face. In patients whose only abnormality is excessive hair on the face, endocrine treatment has not so far proved to be of any use.

The A B C of Syphilis

Q.—*A* is attending *B* for syphilis. *B* is engaged to *C*, a girl of 19. *C*'s mother calls *A* in to see her daughter, who has a "boil on her privates." *A* finds that the "boil" is a primary sore. How should *A* deal with the case, and what should he tell the parents?

A.—1. A should take steps to see that C is adequately treated without delay by either himself or someone else fully competent to do so. Treatment should extend over a period of at least one year and throughout any pregnancy. A should forbid marriage, or at any rate pregnancy, for at least five years.

2. It is probable that B infected C, but it is not a certainty. A should tell the parents that the girl is suffering from primary syphilis, and inform them what that entails in the way of personal hygiene, treatment, postponement of marriage, etc. He should *not* tell them how she may have contracted it, nor should he, without the permission of the parents, tell her fiancé or anyone else that she is suffering from syphilis. He would be wise to obtain their permission to tell B in order that the necessity for postponement of marriage may be explained. In fact A would do well to arrange a conference of the parents, B, C, and himself in order that all necessary arrangements could be made.

INCOME TAX

Adjustment of Depreciation Allowance

"PH" has claimed an adjustment of the depreciation allowance for the past two years, the agreed reductions in the tax paid for those years to be set against the tax for 1943-4. The amounts of the increased allowance are respectively £26 and £48, and in each case the inspector of taxes proposes to deduct 1/10th earned income relief. Is that correct?

•• Yes. If the allowances had been claimed and given in the first instance—i.e., by deduction from the gross assessment—the tax payable would have been affected by 9/10ths of the allowance (e.g., £800 - £26 = £774 less 1/10th would have been assessed), and the same result must be reached if the allowance is given late.

Earnings of Wife—Post-war Credit

E. B. is a married woman and will be assessable for 1943-4 on earnings of £420. She inquires whether the increase in the special personal allowance in respect of wife's earnings—from £45 pre-war to £80—constitutes a set-off from the post-war credit due in respect of earned income relief.

* No. The post-war credit due on the £420 assessment—assuming that tax is paid at 10s. in the £—will be due on (1/6th—1/10th=) 1/15th of £420—i.e., £28 at 10s.=£14.

Failure of Nail Growth

Dr. D. A. MacDONALD writes: The following case has been under my observation for some time, the patient being an N.C.O. For the past 9 months there has been failure of growth of all nails of both fingers and toes. The nails start growing, and after they have reached a length of a few millimetres from the nail-folds they crack and peel off. The nail beds have become dry, and the finger tips and the skin have become hardened and marked. The nail which attempts to grow is soft and pliable and of no thickness. The condition is rather disabling as the toes and fingers are subject to trauma. The patient has been seen by several specialists and the condition has been diagnosed as: (1) vitamin deficiency—a full course of vitamin therapy was instituted with no effect; (2) a fungous infection of the nails—antiseptic treatment has proved useless. The N.C.O. is in perfect health, teeth in good condition, and there are no signs of alopecia. Advice is sought regarding the aetiology of the condition and a possible treatment.

Sterility and Contraception

Dr. V. P. GONSALVES (Nightingale Lane, S.W.12) in the course of a letter on this and other subjects writes: I wrote a letter to you for information about the alleged connexion between contraception and sterility. You either ignored it or perhaps thought it reference to that subject (Sept. 11, p. 350) an adequate reply to my inquiry. But that is merely a statement that your correspondent was not cognizant of any changes therein. But it does not disprove the existence of the power of conception before and its disappearance after contraceptive measures nor the contrary. It is well known that an organ obstructed repeatedly in the performance of its function loses partly or even completely that power—e.g., amblyopic eye with error of refraction or eyes in ponies kept long underground in mines. What changes are visible in the perceptive faculties? These facts may have weighed with the expert gynaecologists whom I mentioned in my letter when they cautiously stated that contraception may possibly lead to sterility. But your correspondent is very dogmatic and states that he has seen no physical changes and therefore no harm has resulted.

Treatment of Gynecomastia

Dr. J. C. JONES (London, S.E.25) writes: I have found that the administration of stilboestrol is effective in the few cases that I have treated in general practice; 2 mg. per day seems to be sufficient.

Survival after Wiring an Aneurysm

Mr. G. H. COLT, F.R.C.S., writes: It might be of interest that the late Sir William I. de C. Wheeler held the world's record for the duration of life, with excellent health and working, of a patient after the wiring of an aneurysm. It was a case of abdominal aneurysm and the man lived 17 years 8 months after the operation. The next longest was Sir D'Arcy Power's—a thoracic aneurysm 10½ years, but in poor health.

Medical Books for Prisoners of War

Since the first appeal in these columns in 1941 for medical books for doctors and others who are prisoners of war, the demand has greatly increased. Many works that are asked for are unobtainable through the ordinary channels, and the Educational Books Section of the War Organization of the British Red Cross and the Order of St. John appeals especially for copies of the following:

Armstrong, Aids to Anatomy and Physiology. Ashdown, M., Complete System of Nursing; Complete System of Nurses. Bantley, J. C., Elementary Practice of Nursing. Bentley, A. O., Principles of Therapeutics. Bertram, Pharmaceutical Chemistry. Borradaile, Zoology. Boydell, The Elements of Laceration, Symptoms and Signs in Clinical Medicine. Copestake, Theory and Practice of Massage. Greisheimer, E., Anatomy and Physiology. Kimber and Gray, Anatomy and Physiology. Knipers, K. D., Essentials of Chiropody for Students. Macaulay, E. I., Textbook for Mental Nurses. Pearce, E. C., Anatomy and Physiology for Nurses; Textbook of Orthopaedic Nursing. Price, Textbook of Medicine. Rose and Carless, Manual of Surgery. Running, E. G. V., Practical Chiropody. Sears, W. G., Medicine for Nurses. Turner, Disease of Nose, Throat, and Ear. Watson-Jones, Fractures and Other Bone and Joint Injuries.

This appeal needs no emphasis from us, but we would ask doctors to look along their shelves to see if they have any of these volumes that they no longer use, or, indeed, any other suitable, medical books. They should be clean, published since 1935, and should not be marked in ink. The address of the Educational Books Section is The New Bodleian, Oxford.

" Morton's Metatarsalgia "

Dr. J. E. J. PALSER (Thecydon Bois, Essex) writes: Mr. W. Sayle Creer (*Journal*, July 24, p. 126) says: "It [*Morton's metatarsalgia*] was first described in 1875 by Prof. D. P. (or T. G.—various books give different initials) Morton." *Gould's Medical Dictionary*, 1941 p. 887, says, "*Morton's disease*—[Thomas George Morton, American surgeon, 1835-1903]. See *M's foot* . . . *Morton's foot*, a painful affection of the metatarsophalangeal joint of the fourth toe metatarsalgia."

LONDON SATURDAY OCTOBER 9 1943

INFECTIOUS MONONUCLEOSIS

WITH AN ACCOUNT OF AN EPIDEMIC IN AN E.M.S. HOSPITAL

BY

JAMES P. A. HALCROW, M.B., M.R.C.P.Ed., D.P.H.
Resident Physician

LLOYD M. OWEN, M.B., Ch.B.
Ex-Resident Medical Officer

AND

NORMAN O. RODGER, M.B., Ch.B.
Medical Registrar

Emergency Medical Service. Scotland

In August, 1942, an epidemic of infectious mononucleosis, presenting some unusual features, was discovered in an E.M.S. hospital, and was also apparently widespread in surrounding districts. During the past few years interest in infectious mononucleosis has increased and many articles have been published. The condition was reviewed in a most comprehensive manner by Bernstein in 1940 and again by Smeall in 1942. Paul and Bunnell, by their discovery in 1932 that the serum of patients with this disease contains an antibody which agglutinates sheep's red cells in high dilution, did much to establish it as a separate entity. The disease may vary in severity from cases with symptoms so mild as to pass unrecognized to an acute illness with severe sore throat, glandular enlargement, and pyrexia, followed by a long period of debility and frequent exacerbations.

Diagnosis

The clinical manifestations are protean, and diagnosis on clinical grounds alone may be almost impossible; examination of a blood smear and a Paul-Bunnell test, however, will soon confirm diagnosis. Tidy, in his papers on this subject, has dealt thoroughly with the clinical manifestations. He subdivides the disease into three groups—anginose, glandular, and febrile types. In the glandular type the onset is usually characterized by slight pyrexia, frontal headaches, and pain and stiffness at the back of the neck. The first glands to be enlarged are usually those in the posterior triangles, often on the left side, and later all other groups of glands may be involved. Glandular enlargement may persist for many months after all other symptoms have disappeared. Tidy states that in about half the cases the spleen is also involved. The anginose type may closely simulate severe acute tonsillitis or diphtheria. Vincent's organisms are often the predominant flora obtained from the throat. The febrile type occurs more commonly in adults, and is characterized by a fairly sharp onset with severe frontal ache and stiffness of the neck. Rashes may occur with this type and may raise the suspicion of typhoid fever, especially if there is splenic enlargement (Tidy, 1934). Moriform and scarlatiniform rashes also occur. In this type, glandular enlargement may not be present until late in the disease and toxæmia and weakness may be prominent features. In all three types various complications may arise: red cells in the urine; epistaxis; purpura; eruptions have been described (Downey and McKinlay, 1931). In some cases the symptoms referable to the central

nervous system may be so severe as to simulate meningitis, and in some there is an increased cell count in the C.S.F. with definite meningitic signs. These cases may closely simulate acute lymphocytic meningitis—here again the Paul-Bunnell test is of great value in differentiation.

Jaundice has been described in infectious mononucleosis, and in these cases catarrhal jaundice may be closely simulated, especially as the blood pictures are not unlike. Bernstein suggests that some cases of catarrhal jaundice with enlarged spleens are probably cases of infectious mononucleosis.

Serological Diagnosis

The Paul-Bunnell reaction is of great value in establishing the diagnosis of infectious mononucleosis. There is, however, much dispute in the literature regarding the titre which can be accepted as diagnostic of the condition. Tidy (1939) regards a titre of 1:64 as specific, but other writers do not accept a titre of less than 1:256 unless the absorption test is also positive. Paul in 1941 stated that a titre of 1:64 is nearly always of diagnostic value, while a titre of 1:32 is suggestive of it. Smeall (1942) gives the results of Paul-Bunnell tests performed on 765 patients not suffering from infectious mononucleosis or serum sickness; in 66.8% of these no agglutination was observed, while only 0.4% gave a titre of 1:64. Barrett in 1941 tested the sera of 100 normal healthy people and found only 4 with a titre of 1:40; none exceeded this figure. Paul and Bunnell in their original work found that 273 control cases gave only low titres. The Paul-Bunnell test may become positive very early in the disease, but in some cases a positive result is not obtained for three to four weeks. In view of this it is essential that in a suspected case of infectious mononucleosis repeated Paul-Bunnell tests be done, as a single negative reaction does not rule out this diagnosis. In cases with a low titre the absorption test is useful to distinguish the infectious mononucleosis antibody. It has been found that sera from cases of infectious mononucleosis contain antibodies which are absorbed by ox cells but not by guinea-pig kidney. Sheep-cell agglutinins occurring in serum from normal people are absorbed by guinea-pig kidney but not by ox cells, while the agglutinins found in the sera of cases treated with horse serum are absorbed by both the ox cells and the guinea-pig kidney (Barrett, 1941).

In cases of infectious mononucleosis in which the Paul-Bunnell titre does not rise above 1:32 this absorption test is of great value. The Paul-Bunnell reaction may remain positive for many weeks after clinical manifestations of the disease have disappeared.

The Blood Picture

Great care in the study of blood films is necessary in establishing a diagnosis of infectious mononucleosis. It is well known that the characteristic finding is a relative and absolute increase of the lymphocytic series of cells. Tidy (1934) states that the total white count ranges between 6,000 and 15,000 per c.mm.; in many instances, however, the count has greatly exceeded this figure. Rarely, the disease may be ushered in by a leucopenia. Paul (1939) noted that in about half his cases leucopenia was a feature. Tidy mentions that the polynuclear cells often show a shift to the left, and he draws attention to the statement that the eosinophils may be low or absent during the acute stage and increased above normal during convalescence. Tidy also mentions the initial polynucleosis at the onset of the disease. It is, however, in the mononuclear cells that striking changes occur: these cells often constitute 60% and upwards of the total white count (Bernstein, 1940). Bernstein comments on the fact that mononucleosis occurs more commonly in sporadic cases than in the epidemics, and he attributes this to the fact that only the more obvious cases of the sporadic type are recognized, while in a known epidemic slight changes in the blood are looked for and found.

The mononuclear cells in infectious mononucleosis may be divided into three groups: Group 1, normal lymphocytes; Group 2, monocytes; Group 3, abnormal or atypical lymphocytes. Groups 1 and 2 correspond to cells found in normal blood. The atypical lymphocytes show great variation in morphology; they vary in size and shape, and the nucleus may be oval, indented, or show lobulation. Nuclear chromatin often shows fenestration. Downey in 1923 divided abnormal lymphocytes into three types: Type 1 corresponds to the cell described above, and in Type 2 cells the chromatin of the nucleus is not so condensed and the cytoplasm does not show vacuolation; Type 3 cells resemble those of acute lymphatic leukaemia, the nucleus possessing nucleoli and a basophilic cytoplasm. It is generally agreed that the erythrocytes and the platelets are not affected in infectious mononucleosis, and bleeding and coagulation times are normal. The blood picture typical of infectious mononucleosis is characterized by a relative and absolute lymphocytosis and the presence of abnormal lymphocytes.

Many writers describe cases of infectious mononucleosis in which serological tests for syphilis have been positive. Bernstein states that 18% of his cases were serologically positive for syphilis, while Radford and Rolleston drew attention to this phenomenon in 1930. Paul in 1939 described several cases in which a positive Wassermann reaction was obtained. Kahn in 1939 drew attention to the fact that these false positive serological tests for syphilis may persist for several months.

The Marrow

Freeman in 1936 found an increase in lymphocytes and sometimes a slight shift to the left of the myeloid leucocytes in marrow from cases of infectious mononucleosis. Israël in 1941 found, in a few cases he examined, that the marrow showed an increase in plasma cells and abnormal lymphocytes; Vogel and Bassen in 1939, however, in four cases found no change in the marrow. Sternal puncture would certainly help to differentiate between acute lymphatic leukaemia and infectious mononucleosis.

Pathology of Lymph Glands

All authors agree that there is marked hyperplasia of lymphoid and reticulo-endothelial cells. Pratt in 1931 described great hyperplasia of the reticulo-endothelial cells. Downey and Stasney referred to similar pathological findings in 1936. Longcope in 1922 gave an essentially similar picture. The gland architecture is maintained, and the abnormal lymphocytes found in peripheral blood can be demonstrated throughout the glands (Gall and Stout, 1940).

The changes found in lymph glands are not diagnostic, and could be confused with any non-specific adenitis, although biopsy of a lymph gland would readily differentiate between infectious mononucleosis and more serious conditions such as lymphatic leukaemia and lymphadenoma.

Most epidemics of infectious mononucleosis have occurred among children. Tidy and Morley (1921) reckoned that 85%

of epidemic cases of this disease occurred in children under years of age. Nolan in 1935 described an epidemic of infectious mononucleosis in which only 5 cases out of 220 in adults. The Paul-Bunnell titres in his cases ranged 1:80 to 1:320, and most of the cases appeared to be mild. Most epidemics of infectious mononucleosis have occurred in hospitals and institutions. The incubation period usually from 5 to 11 days. Boyd (1940) states that studies of a healthy medical students during an epidemic show many mild cases probably pass undiagnosed. Keyersbael and Lenert (1941) describe 16 cases among 108 children who receiving convalescent treatment after rheumatic fever. Of these 16 cases showed symptoms or signs; the blood picture was apparently typical, although the predominating cell the small lymphocyte and the Paul-Bunnell reaction negative. Smith (1941) describes leucocytosis with absolute lymphocytosis occurring in children without symptoms of disease being manifest.

Description of the Epidemic

The epidemic described below differs in many respects those previously recorded. The age incidence was from 14 to 45 years; the outbreak occurred in a selected population, young soldiers who, although in hospital, were relatively healthy. The disease was distributed equally between males and females. Two older cases may be specially mentioned here: one that of a woman aged 84 who had no clinical manifestations of the disease, but had a Paul-Bunnell reaction of 1:128; another of a woman aged 65%; the other was that of a woman aged 48% who had no clinical manifestations, a negative Paul-Bunnell reaction, but a very typical blood picture with a mononucleosis of 48%. These patients were the oldest observed. The incubation period in our cases varied from 5 to 10 days; in this instance it was exactly 5 days.

The most interesting feature of the epidemic was the occurrence of cases without clinical manifestations. In many instances the Paul-Bunnell antibody was present along with typical blood changes—i.e., a relative and absolute mononucleosis with abnormal lymphocytes present in the peripheral blood—but clinical manifestations were completely lacking.

The first case to be detected in this outbreak was that of a woman aged 25, admitted to the hospital on Aug. 5, 1942, with a clinical attack of severe anginal infectious mononucleosis. She had a mononucleosis of 83% and her Paul-Bunnell reaction was five times at 1:340. Four other cases were also admitted to the medical unit early in August. On Aug. 12 one of the male medical staff who was in close attendance on the first patient began to show symptoms of the disease, although he made no special comment until Aug. 23, when he had generalized glandular enlargement. From Aug. 12 onwards many members of the nursing medical staff began to suffer from moderately severe symptoms of infectious mononucleosis, and cases also occurred among the medical patients. As the infection seemed to be widespread, blood pictures were examined from all patients in the unit at this time, with the astonishing result that every one was found to have a blood picture typical of infectious mononucleosis, although many were symptomless. On Aug. 26 it was decided to take sample blood pictures from all patients in other units of the hospital, and these again showed blood picture typical of the disease. As a great number of medical staff and patients were now complaining of symptoms it was decided to close the hospital to admissions from Aug. 28, and a thorough investigation was made into the outbreak. At this time 273 patients in the hospital were examined clinically for symptoms and blood pictures, and 97% were found to have infectious mononucleosis and, so far as time permitted, Paul-Bunnell tests were done, together with blood examination. In addition, members of the medical and nursing staffs were investigated, making the total 296. The result revealed that 97% of those investigated showed evidence of the infection. In no instances could the infection be completely excluded; these persons had no symptoms or signs and had normal blood pictures with titres or negative Paul-Bunnell reactions. Of the 296 persons investigated at this time 125 were clinical cases of infectious mononucleosis, and 165 had blood and serological changes but no clinical manifestations of the disease. In addition, relatives of the medical and nursing staffs living outside the hospital developed clinical manifestations of the disease which were quite well marked. Previous epidemics of infectious mononucleosis have been described but none appears to have reached the high percentage of positive cases present in this epidemic. It would seem that the infection was very high, or else the hospital and surrounding districts were subjected to a very heavy dosage, perhaps due to blood conditions.

Cases can be subdivided into groups according to the highest titre of the Paul-Bunnell test.

TABLE I.—296 Cases, plus 23 in which no Paul-Bunnell Tests were Done

Distribution of Cases	Paul-Bunnell End Titre					Paul-Bunnell not Done, but Blood Picture Typical
	1:512	1:256	1:128	1:64	1:32	
Medical unit ..	7	9	25	24	5	3
Aver. W.B.C. ..	10,900	6,600	10,900	9,400	9,900	9,900
mononuc. ..	49%	49%	46%	47%	49%	47%
Orthopaedic unit ..	4	12	34	52	49	22
Surgical unit ..	0	6	16	13	8	3
Cases with clinical manifestations ..	9	15	40	40	16	5
Total cases ..	11	27	75	89	62	23

The cases in the medical unit include members of the nursing and medical staffs. Of the six cases which were entirely negative, five were in the orthopaedic unit and one in the surgical unit. All six negative cases had Paul-Bunnell titres of 1:32 or less. In Table I 23 additional cases are shown: these cases had no Paul-Bunnell tests, but their blood pictures were characteristic. The surgical unit is closely adjacent to the medical unit, in which infection was most severe; the main part of the orthopaedic unit is 1,000 yards away from the medical unit. All the surgical staff of the surgical and orthopaedic units had clinical manifestations of the disease.

As the infection seemed widespread in the hospital it was decided to use as a control group of cases elsewhere, and Dr. E. Neil Reid, County M.O.H., kindly gave us facilities to examine cases in centres at varying distances away. The first group—19 A.R.P. workers—examined was in a town closely adjacent. Paul-Bunnell tests, white blood counts, and differential counts were done on all of them. Of these 19 cases (Table II, Group A), 7 were in close contact with the hospital, and most of the others had opportunities to contact its personnel. A further control group (B) was examined in a town about 5 miles from the hospital, this being the place from which the first severe anginose case was admitted. Group C was drawn from an A.R.P. group in a town about 13 miles and Group D from a small country village about 20 miles from the hospital. In addition, the Department of Health for Scotland arranged for a control group (E) in another E.M.S. hospital about 35 miles distant, and we are indebted to the Department for the results shown in Table II.

TABLE II.—Results of Control Investigations

Group	No. of Cases	Paul-Bunnell Titre				Blood Picture		Clinical Manifestations	
		1:256	1:128	1:64	1:32				
A & B	37	6	12	7	8	3	37	2	35
C & D	35	—	1	3	10	21	31	2	33
E	20	—	—	—	—	20	20	—	20

Clinical Features

Clinically, cases can be divided into four groups:

1. *Latent Cases.*—Cases with a relative or an absolute mononucleosis with abnormal lymphocytes present and a positive Paul-Bunnell reaction, but in which there were no symptoms or signs of the disease.

2. *Mild Cases.*—Cases with symptoms and signs, but not so severe as to lead to abstinence from duty, or would not have done so if the patient had not already been in hospital with some other complaint.

3. *Moderate Cases.*—Similar to Group 2, but with severer symptoms and patient confined to bed for a day or two.

4. *Severe Cases.*—Patients more seriously ill, and diagnosis found difficult.

Symptomatology

Headache.—This was present in 92 cases and was severe; it was frontal in distribution, intermittent in character, and tended to recur daily for several days. Pain behind the eyes was often severe, and a mild conjunctivitis was present in a fair number of cases.

Stiff Neck.—Common, and probably due to the enlarged glands. Definite nuchal rigidity was observed in two cases.

Mental Symptoms.—These occurred in 31 cases, and consisted of slight confusion, inability to concentrate, transient forgetfulness, lassitude, and insomnia.

Pyrexia.—This was not a feature except in anginose cases. In one case pyrexia was the only feature, and continued for many days before glands became enlarged. Another glandular case had pyrexia without the illness.

Polyuria with Lumbar Pain.—Occurred in 34 cases. The urinary findings were negative except in anginose cases in which red cells and albumin were present in the urine.

Glands.—The lymphatic glands were enlarged in nearly all cases, although enlargement had sometimes to be sought for carefully. The glands were fleshy and usually tender, and the groups most frequently involved were in the posterior triangles of neck and axillae, although many cases had generalized glandular enlargement, often including the epitrochlear glands. Glandular enlargement was intermittent, with a tendency to frequent relapses. In cases from which glands were removed for biopsy it was noted that healing was very slow although no sepsis was present. In one case healing occurred only after blood transfusion, but was then rapid. Whitby and Britton (1939) state that glands should not be excised.

Spleen.—Splenic enlargement was present in about 30 cases, but many others had pain and tenderness in the left hypochondrium. In one case the spleen reached to below the umbilicus.

Rashes.—These were observed in 10 cases. (a) Maculo-papular—seen in 3 cases. In two cases the rash began between the scapulae and spread on to the front of chest and abdomen, later spreading to the upper part of arms and legs. In these two cases there was no rash on the hands, legs, or face. In the third case the rash started in the front of the body and spread round to the back and on to the flexor aspects of the arms. These three cases could have been confused with secondary syphilis, as sore throat and generalized glandular enlargement were a feature. However, the W.R. was negative, the Paul-Bunnell titre was positive at 1:256 or over, and the blood pictures were quite typical. The rashes occurred early, usually on the first or second day. (b) Scarlatiniform and morbilliform rashes were seen in the remaining 7 cases, and these rashes were very transient. (c) One case with a purpuric rash on the legs and thighs was observed.

Jaundice.—This was not seen during the epidemic, but the icteric index and the van den Bergh test, done on 15 of the severer cases, showed that 8 had latent jaundice. One case admitted after the hospital reopened had fairly severe jaundice, serum bilirubin 6 mg. per 100 c.cm., and a Paul-Bunnell titre of 1:128 with a positive absorption reaction.

Sore Throat.—Present in 35 cases. The fauces were injected, but only 4 true anginose cases were seen.

Alimentary Symptoms.—Transient diarrhoea was present in 13 cases in the early stage of the disease. Vomiting was also present, and in a few cases vomiting and diarrhoea were severe. Repeated examinations of the faeces for pathogenic organisms in these cases were negative.

Thoracic Symptoms.—Observed in many cases, and often raised the suspicion of pleurisy or pneumonia. Pain in the chest, aggravated by respiration and accompanied by cough, was the main symptom. Clinical and radiological examination of these patients was negative. It seems likely that the symptoms were due to enlarged mediastinal glands, although this was not confirmed on fluoroscopy.

Meningitic Cases.—In 5 cases meningitic symptoms were severe enough to warrant lumbar puncture. In 4 of these cases the C.S.F. pressure was high, and three of these four had a cell count above 5 per c.mm., while the one with normal cell count had an increase in protein. In the fifth case the C.S.F. was normal in every respect.

Epistaxis.—Observed in 4 cases.

One case was observed in which the salivary glands were enlarged; the blood picture was typical and the Paul-Bunnell titre 1:128. Six cases with parotid enlargement were described by Glanzmann in 1930.

In most cases the symptoms subsided completely within 5 to 21 days, but a few went on for longer periods, with relapses, and two were still having relapses after six months.

The Wassermann, Kahn, and flocculation tests were done in many cases during the epidemic and were consistently negative, irrespective of the titre of the Paul-Bunnell; thus the results differed from those obtained by other workers. In 6 cases recently observed by us in which the absorption test for the glandular fever antibody was positive, the W.R. and the flocculation test were negative throughout the course of the disease. In two of these recent cases the Paul-Bunnell titre exceeded 1:2000.

The Paul-Bunnell Test

During the first three weeks of the epidemic about 1,000 Paul-Bunnell tests were done, and in these circumstances it was impossible to put up the serum in dilutions greater than 1:512. The patients' sera were inactivated at 55° C. for 15 minutes, and dilutions of the sera ranging from 1:32 to 1:512 were set up; to these 0.5 c.cm. of 1% suspension of washed sheep red cells was added. The tubes were then placed in the incubator for one hour and afterwards left in the refrigerator all night. After shaking gently two or three times they were read by naked eye, according to the method of Paul and Bunnell. Any result about which there was the least doubt was regarded as negative. Unfortunately, at the time the epidemic was in progress it was not possible to do absorption tests to prove the presence of the true glandular fever antibody. However, one of the patients seen during the epidemic returned to hospital in the middle of December, and the Paul-Bunnell reaction on this occasion was positive 1:32, and the absorption test, using guinea-pig kidney and ox cells, was positive (Barrett, 1941). Much has been written about the diagnostic titre in the Paul-Bunnell reaction. We agree with Tidy that a titre of 1:64 is practically diagnostic. We think a titre of 1:32 is suggestive and is an indication for repetition of the test in a few days' time. In many of our cases the first two or three Paul-Bunnell tests, performed at intervals of 5 to 7 days, were negative at 1:32, and thereafter gradually rose to significant or diagnostic titres. The titres observed in this epidemic are low compared with those of sporadic cases, but are much higher than titres obtained in control groups of cases not suffering from infectious mononucleosis and described by other writers. In our series of 296 cases 202 had titres of 1:64 or over—a finding quite unlike anything previously described on controls done on normal people. It is strong evidence of the presence of some infective agent which has greatly increased the heterophile antibody response in our cases; when coupled with the clinical findings and the blood picture the evidence that the disease present was infectious mononucleosis is almost certain.

The Blood

Blood changes in infectious mononucleosis have been considered very thoroughly by various authors, and the changes found in this epidemic were much in accordance with previous descriptions.

In our series the total white count varied from 8,000 to 20,000, but only a few cases had counts of 20,000. Many had leucopenia fairly early in the disease, as found by Tidy, by Longcope, and by Davidsohn (1937). An initial polymorphonucleosis was seldom observed in this epidemic. In most of our cases the polymorphs showed a shift to the left, and stab cells were often seen; many of the polymorphs showed toxic granulation. Early in the disease we observed that eosinophils were absent; but later on, as recovery ensued, they returned in proportions greater than normal. An unusual feature was an increase in basophils, these ranging from 1 to 3% in a fairly early stage of the disease.

The platelet count and coagulation time (Lee and White) were unaffected. Anaemia was not a feature: one case of hypochromic anaemia occurred in a young adult male; this responded rapidly to iron therapy. In a female anginose case anaemia was severe and the white cells fell to 2,000, which led to a suspicion at first of agranulocytosis, especially as the abnormal cells of infectious mononucleosis have been described as occurring in agranulocytosis.

The mononucleosis varied from 45 to 60%—only in a few cases did it exceed 75%. The most striking change in the lymphocytic series of cells was the almost complete disappearance of small lymphocytes; this occurred early in the disease. The other feature was a marked increase in the numbers of large lymphocytes and the appearance of abnormal lymphocytes. Many of the large lymphocytes had a very pale cytoplasm with the typical pale nucleus of the normal large lymphocyte—in most respects they did correspond to the normal large lymphocyte except that the cytoplasm was paler than usual and often vacuolated. Many of them contained the normal reddish-purple granules in their cytoplasm. Some of the large lymphocytes appeared to be unduly fragile. Films made from early cases contained many smear cells.

The abnormal lymphocytes varied greatly in morphology—in size they ranged from a cell intermediate between a large and small lymphocyte to a large monocyte. The cytoplasm was usually much more basophilic than that of the ordinary lymphocyte and was nearly always vacuolated. Some of the abnormal cells were difficult to distinguish from plasma cells. The nuclei varied greatly in shape—some were oval or rounded, others irregular or lobulated. The nuclear chromatin was dense. Some of the abnormal lymphocytes had irregularities of their cytoplasm which resembled pseudopodia. Many of the abnormal lymphocytes seen corresponded to Downey's Type I and Type II; only in a few cases was Downey's Type III evident. Peroxidase staining failed to reveal any granules in the cytoplasm of the abnormal lymphocytes.

Blood changes usually persisted for several weeks, and a fair proportion of cases still had many abnormal cells present at the end of three months. A true monocytosis was not a notable feature; it occurred late and usually varied from 10 to 13%. An interesting phenomenon previously noted by Barrett was confirmed in this outbreak: the typical blood changes may be present before clinical manifestations make their appearance. This was noted in several cases.

In most of our cases the sedimentation rate was not affected: only in anginose cases and those with pyrexia did the B.S.R. increase. In one case with pyrexia, severe meningitic manifestations, and a C.S.F. cell count of 300 lymphocytes per c.mm the B.S.R. never rose above 4 mm. per hour (Westergren).

Sternal puncture was performed on several cases. Examination of the marrow revealed a definite increase in lymphocytic cells and a slight increase in activity of the myeloid series of cells. In some marrow specimens there was an increase of cells of the plasma cell type, and cells resembling the abnormal lymphocyte in the peripheral blood were also noted. These findings correspond to those of Israëls (1941). It is proposed however, to deal with the findings in a separate paper at a later date.

Pathology of Lymph Glands

Biopsy of lymph glands was performed on several cases, and reports of two, with case histories, are as follows:

Male aged 27.—Sept. 16, 1942: Sore throat and frontal headache; pain in back and axillae. Glands palpable in both axillae. During next 14 days nausea, headache, and pain in axillae and groins were present, and on Sept. 27 there was generalized glandular enlargement with slight splenomegaly. Blood examinations: Sept. 15: W.B.C. 10,600—polymorphs 70%, large lymphocytes 10%, small lymphocytes 2%, monocytes 5%, abnormal lymphocytes 13%. Sept. 23: W.B.C. 12,000—polymorphs 57%, large lymphocytes 11%, small lymphocytes 2%, eosinophils 2%, basophils 1%, monocytes 10%, abnormal lymphocytes 17%. Paul-Bunnell tests: Sept. 9, 1:64; Sept. 23, 1:128; Sept. 30, 1:128; Oct. 17, 1:32.

Report on Gland from Left Axilla.—Well-marked hyperplasia of the lymphoid tissue is present, many of the germinal centres being very large and prominent. A number of the sinusoids show moderate but distinct dilatation and are packed with numerous reticulo-endothelial mononuclear cells, together with a moderate number of small lymphocytes. Scattered areas of old fibrosis, presumably post-inflammatory, are also present.

Man aged 23.—Sickened Sept. 12, 1942, with severe frontal headache, shivering attacks, and pain in both groins. Eyes sore and watering. Glands palpable in both anterior and posterior triangles of neck and in both groins; later developed slight splenomegaly. A blood examination the same day showed: W.B.C. 18,450—polymorphs 69%, large lymphocytes 15%, small lymphocytes 2%, eosinophils 2%, basophils 1%, monocytes 1%, abnormal lymphocytes 10%. Paul-Bunnell tests: Sept. 10, 1:128; Sept. 22, 1:64; Oct. 11, 1:64.

Report on Gland from Right Groin.—Lymphoid hyperplasia is present, but is not a prominent feature. Sinusoidal dilatation is, however, much more conspicuous than in the preceding case. The dilated sinusoids contain numerous reticulo-endothelial mononuclear cells, together with a moderate number of small lymphocytes.

We are indebted to Dr. W. Forbes, Department of Pathology, Edinburgh University, for the report on these glands. The changes described in the glands correspond to previous descriptions. They cannot be regarded as specific.

Treatment

In our cases treatment was mainly symptomatic. In two anginose cases sulphapyridine was given, but no favourable

response was obtained; in fact, in one case the throat condition became worse, pyrexia continued, and blood transfusion had to be given. As the granulocytes are reduced in infectious mononucleosis and many show toxic changes, it is not surprising that sulphonamides do not give good results. Tidy (1941) states that if granulocytes are normal or increased in number no harm is done with sulphonamides. He has seen cases made worse by sulphonamides. Convalescent serum was not used. One case with fairly severe meningeal symptoms, pyrexia, and raised C.S.F. cell count made a rapid response to sulphadiazine.

Discussion

The unusual features in this epidemic were the high infectivity and the presence of latent cases. Before the epidemic started 5 known cases of infectious mononucleosis were admitted to the medical unit. This would increase the chances of spread considerably, but it hardly accounts for cases elsewhere in the hospital and outside. It seems likely that the district had an epidemic of mild infectious mononucleosis which was fairly localized. In view of the protean manifestations of the disease and the difficulty of diagnosis in the absence of haematological and serological tests the outside cases would be regarded as influenza, gastro-enteritis, etc. The difference in the findings between the outside controls near the hospital and those situated at some distance is very striking, and points to a definite localization of the disease. The spread of the epidemic within the hospital is difficult to follow. Efforts to trace case-to-case infection did not meet with any satisfactory result.

Latent cases can be explained on the basis that their immunity was sufficient to prevent the onset of clinical manifestations, as in the manner of diphtheria and meningococcus carriers. In infectious mononucleosis, however, the presence of the infecting virus produces changes in the blood picture and stimulates the production of heterophile antibodies so that latent cases are easily detected.

Differential Diagnosis

Epidemic infectious mononucleosis in adults is a relatively mild condition which simulates many other conditions. The anginous type resembles diphtheria, but here the blood picture is useful to distinguish these conditions: in diphtheria a polymorphonucleosis is invariable, while in a fully developed anginoid infectious mononucleosis absolute lymphocytosis is the rule. The cerebral type may closely simulate a true septic meningitis, but although the cell count may be raised to 300 or 400 per c.m.m. the predominant cell is a small lymphocyte. This, of course, still leaves it doubtful whether or not it is a tuberculous meningitis; to exclude tuberculous meningitis the blood picture and Paul-Bunnell test are of undoubted value. In one of our cases with meningeal symptoms the C.S.F. cell count was 400 per c.m.m. and optic neuritis was present for 8 weeks; the patient also had glandular enlargement, with the usual haematological and serological findings, and made a complete recovery. Cases with thoracic symptoms may simulate pleurisy or pneumonia, while those with severe vomiting and diarrhoea may closely resemble acute gastro-enteritis or typhoid fever.

The blood picture in infectious mononucleosis may be simulated to a certain extent in other conditions, particularly catarrhal jaundice and atypical pneumonia. In catarrhal jaundice abnormal lymphocytes are not infrequent, but here the Paul-Bunnell test and the absence of glandular enlargement help to differentiate the two conditions. In four cases of atypical pneumonia seen by us there was an absolute lymphocytosis, and abnormal lymphocytes were present; some of these had a deeply basophilic cytoplasm and were in many respects similar to the abnormal lymphocytes of infectious mononucleosis. However, in all four cases the Paul-Bunnell test was negative and glandular enlargement was absent. Downey and Stasney have commented on the presence of abnormal lymphocytes in agranulocytosis, a condition which may also simulate anginous infectious mononucleosis. In cases with a rash the diagnosis of secondary syphilis, rubella, or erythema nodosum may be considered. Rubella may be very difficult to differentiate from infectious mononucleosis: in both conditions the posterior triangle glands are enlarged, and the rash of

rubella may be closely simulated in infectious mononucleosis. In rubella the peripheral blood contains many Türk cells and abnormal lymphocytes, rather resembling those of infectious mononucleosis. However, the Paul-Bunnell reaction is of undoubted value, as it is consistently negative in rubella. In three cases of rubella seen by us the Paul-Bunnell test was negative throughout the disease. The rash in infectious mononucleosis may often resemble that of typhoid; and here the diagnosis may be difficult, as false positive Widal tests have been reported in infectious mononucleosis by Bernstein. Again the Paul-Bunnell test is very useful. The more serious blood disorders, such as leukaemia, should never be confused with infectious mononucleosis, for, as Smeall pointed out in 1942, the changes in the red cells in leukaemia make the distinction quite clear. In general it may be said that the diagnosis of infectious mononucleosis should not be made on any one test: the Paul-Bunnell reaction, the haematological findings, and the clinical manifestations should all be correlated before coming to a decision.

It seems likely that infectious mononucleosis, especially in a mild form, is a very common condition which can readily be mistaken for other diseases. Since the hospital reopened we have seen a number of cases of infectious mononucleosis, many of which would have been regarded as some other condition unless blood counts and Paul-Bunnell tests had been carried out.

Summary

An epidemic of infectious mononucleosis is described.

The unusual features were: (a) a high percentage of infected cases in the adult population; (b) the occurrence of cases with haematological and serological findings and no clinical manifestations; (c) the fact that blood and serological changes may precede clinical manifestations.

Attention is drawn to the difficulties in diagnosis, and the necessity for repeated Paul-Bunnell tests before excluding the disease.

The condition is always benign and does not respond favourably to sulphonamide therapy.

We are much indebted to the following for their help and advice: Prof. L. S. P. Davidson, Dr. J. L. Halliday, Prof. T. J. Mackie, Dr. A. A. F. Peel, and Dr. I. S. Sutherland; and to Dr. J. A. Jenkins, medical superintendent, and our colleagues in the hospital for their co-operation and help. We are indebted also to the Department of Health for Scotland for permission to publish this paper.

Dr. E. H. Claver's report for the year 1942 as Director of the South African Institute for Medical Research, Johannesburg, includes a section on war work. There has been further expansion in various branches of the Institute's activities to meet increasing military needs. Vaccines and sera produced under normal conditions for civilian requirements were wholly inadequate in quantity to cope with the special hazards to which campaigning troops are exposed. Their production had to be enormously increased and new procedures had to be introduced; for example, anti-gangrene serum, not prepared locally before the war, is now being produced on a very large scale. A military Directorship of Pathology, under Dr. Claver as honorary colonel, was set up to undertake the training of staff for the various military hospital laboratories and to supervise their equipment and running.

A NEW APPROACH TO THE TREATMENT OF EARLY SYPHILIS BY INTENSIVE THERAPY

BY

T. R. LLOYD JONES

Surg. Capt., R.N.; Consultant in Venereal Diseases, Royal Navy

AND

F. GORDON MAITLAND

Surg. Lieut.-Cmdr., R.N.V.R.

Our purpose in writing this paper is to present a new understanding of "early syphilis" and of its treatment by a modified form of intensive therapy, with the result of work and investigations done on a series of 100 cases. Our aim has been to try to evolve a scheme of treatment which, while promising to be adequate and effective, may at the same time reduce the toxic effects of existing methods to a minimum.

It has been universally accepted that the earlier syphilis is diagnosed and treatment begun the greater the percentage of cure. But that syphilis can be aborted is proved by:

1. Magian's (1919) self-inoculation experiment with *Spirochaeta pallida*—namely, a single injection of arsphenamine given one hour after inoculation and no subsequent relapse.
2. Fournier and Guenot's (1919) experiments with 40 women treated with from four to six injections of arsphenamine, 20 of whom, followed up, remained free from syphilis for three years after having been infected up to three weeks previously by men with proved contagious genital lesions, while those who refused treatment under exactly similar conditions all subsequently developed syphilis.
3. Paul Padgett's (1941) dictum that patients who received as little treatment as only from four to six injections of an arsphenamine by conventional divided-dose technique have a 60% chance of a five-year cure.

Accordingly we have tried to find out whether there is any reliable guide to the stage of infection that can be aborted by some such small-dosage method.

Moore *et al.* (1941a) state: "It is unfortunate that no method exists by which the probable cures after small amounts of treatment can be picked out before or during treatment, and that this hiatus in our knowledge is responsible for the undoubted fact that some patients receive much more treatment than is actually necessary." We believe that the selection of cases stressed by Moore can be achieved by performing a daily quantitative serum test for syphilis (D.Q.S.T.S.) as evaluated by a Kolmer-Wassermann or some other equally sensitive test. It is on the results of this D.Q.S.T.S. that we have evolved an original line of approach to a more exact method of diagnosis and treatment of early syphilis.

Diagnosis

The Q.S.T.S. performed daily on patients undergoing intensive treatment with the single daily injection has resulted in certain definite findings. These findings can be placed in three main categories.

Category I—the early primary—is that in which the serum of a patient during treatment remains at a constant negative level. There can be no syphilitic reagin present in the serum or it would give a positive or doubtful reading.

Category II—the middle primary—is subdivided into two types. Type A is that in which there is an initial negative phase persisting for anything up to five days after the institution of treatment, followed by a sharp rise to the positive zone. This, persisting for sometimes up to eight days and not reaching above a titre of 17, given by tube readings of 4, 4, 4, 4, 1—i.e., 25% inhibition of haemolysis in fifth tube, which contains 0.005 ml. of serum—reverts immediately to negative before the completion of treatment and, except perhaps in some cases for a slight secondary very transitory rise, remains negative subsequently. Type B is that in which the titre is already rising at the beginning of treatment, but its subsequent behaviour is exactly similar to Type A. This Category II appears to be one which has so far escaped notice, as it must inevitably do when blood tests are taken at weekly or longer intervals.

The table on p. 450 shows that this "middle positive phase" has occurred in 19 of our cases, and a possible explanation should be

attempted. We feel that this positive phase: (1) Is not a technical error within the limits of the test (cf. "Laboratory Routine," para. 8), (2) Is not connected with a Herxheimer reaction. Only one of the middle primary cases has had a Herxheimer reaction, and his positive phase did not take place until the fifth day of treatment. (3) Is not due to any provocative drug action, as, if it was, it would show very much more frequently and at the expense of the early primary group. A provocative effect after an injection of arsenic is now disputed, and is considered to be fallacious (Moore *et al.*, 1941b).

An explanation is that it may well be an "abortive" phenomenon—the early injections not being sufficient to prevent completely the potentially rising titre, but with succeeding doses the positive phase is overcome. But for treatment, such a serum would presumably continue to rise to the high titre of the late primary. It is more than a coincidence that this phenomenon has appeared in one out of every five cases. It is a group which to us seems to be of great importance, as it is a link between the early primary and the late primary groups; unless recognized and treated appropriately it may well be a potential source of relapse.

Category III—the late primary—also occurs in two types. Type A is that in which the serum has already reached a high titre before treatment. This type remains at a consistently high level, which may be maintained for an indefinite period but which eventually reverts to negative. This may take place just before the end of treatment or later, within a period of six months. This fact is important, as, provided a patient with late primary has received his estimated dosage of arsenic, the positive serum should merely be controlled and not considered as an indication for further anti-specific treatment in the absence of negative clinical signs and within this time period. In Type B the titre rise takes place just after the initial injections and remains consistently at a high level for a period of approximately three weeks before reverting to normal thus differing from the middle primary Type A, which shows only a very transitory positive phase before falling again to negative. In our series of Type A cases the serum has reverted to negative in a much shorter time than six months, probably because patients report for treatment earlier than is the case in civilian practice.

For clarity in demonstrating these three categories a graph is drawn for each patient, using the date line as the ordinate and the quantitative titre reading as the co-ordinate. This forms a simple guide to the visualization of the separate group readings.

GRAPH I.—Early primary (Category I). Incubation, 6 weeks; *Sp. pallida*, none found at 20 hours; total mapharside dose, 580 mg.; days under treatment, 10.

GRAPH II.—Middle primary, Type A (Category II, Type A). Incubation, 6 weeks; *Sp. pallida*, none found at 30 hours; total mapharside dose, 970 mg.; days under treatment, 20.

Our series further demonstrates that there is no definite constant relation between the incubation period of the first clinical sign—the sore—and the appropriate category. Thus in 35 early primary cases the average number of days' incubation of the sore was 27.5, varying from 8 to 63; of 16 middle primary cases 34.9 days, varying from 5 to 84; and of 31 late

primary cases 61.2 days, varying from 21 to 112. No incubation period could be determined with certainty in a few of the series because of marital relation, frequent exposures, loss of memory," etc. It seems that there must be some human factor of resistance present for the incubation of the primary lesion. Another point of interest is that during positive phases there does occur, in many cases, a daily variation in the amount of reagin present in the patient's serum.

GRAPH III.—Middle primary, Type B (Category II, Type B). Incubation, (1) 10 days, (2) 4 weeks; *Sp. pallida*, none found at 16 hours; total mapharside dose, 940 mg.; days under treatment, 20.

GRAPH IV.—Late primary, Type A (Category III, Type A). Incubation, 6 weeks; *Sp. pallida*, none found at 16 hours; total mapharside dose, 1,430 mg.; days under treatment, 30.

GRAPH V.—Late primary, Type B (Category III, Type B). Incubation, ? 1 month; *Sp. pallida*, none found at 18 hours; total mapharside dose, 1,300 mg.; days under treatment, 30.

Treatment

Moore *et al.* (1941c), Chargin (1940), Shaffar (1943), and others have pointed to the increased toxicity of neoarsphenamine as compared with arsenoxide for use in intensive therapy, so mapharside was decided on as the most suitable preparation for our purpose. In fact, in the Royal Navy mapharside is the drug of choice, and is replacing neoarsphenamine in routine use.

It is usual in courses of intensive treatment to give a dosage of 200 to 1,800 mg. of arsenoxide for all types of cases: primary, secondary, and early latent syphilis indiscriminately. It is, therefore, a fixed predetermined dosage for all types of cases. "Early sero-negative" responsive cases have to risk large drug doses necessary for the resistant case—a dose, hence, associated with all too high mortality and toxic rates. We believe this predetermined fixed dosage for all types of cases to be illogical. Dosage should be regulated according

to the categorized type. Before this investigation was started no control of minimum dosage had been tried on a series of early syphilis differentiated into definite types, but it is only rational to think that an early primary case with a consistently negative blood Kolmer-Wassermann reaction should require a smaller dose than a middle primary case having a positive blood phase—likewise, a middle primary should require less than a late primary having a consistently high serum titre: all presumably representing different degrees of intensity of infection. On this deduction we have based our scale of dosage.

The early primary cases are regarded as a group which can be aborted and so require a small abortive dosage. The middle primary requires a slightly higher dose that is still considered an abortive dose; while the late primary—the well-established group—requires a curative dosage. We began by giving the early primary case a total of 600 mg. in 10 daily injections; but this has now been revised to 15 daily injections of 0.04 g. to 0.06 g.—a total of 600 to 900 mg., depending on the patient's weight. This alteration was made for two reasons: first, because we felt that a small daily dose given over a slightly longer period would lessen the likelihood of toxic effects; secondly, because we had three relapses. However, in fairness to ourselves it should be mentioned that at the beginning of our investigations a less sensitive Wassermann technique than the Kolmer-Wassermann was in use, so these three relapses may well have been missed middle primary cases, but treated with the early primary dosage; this would account for the relapses. The important point is that no relapse has occurred since the introduction of the Kolmer-Wassermann quantitative test. This may, however, be pure chance, as the numbers so far treated have been small.

Not having any previous guide to an abortive dose apart from Padgett's (1940) conclusions, the above dosage was decided upon somewhat empirically, and is subject to revision as experience and results justify. For the middle primary a slightly increased dosage was considered necessary because of the positive phase; accordingly 20 daily injections of 0.04 to 0.06 g.—totalling 800 to 1,200 mg.—were given, depending again on body weight. Originally these injections were given as two series of ten with a rest period; this has now been altered to consecutive doses.

For the late primary a still further increase was necessary, and so 30 daily injections of 0.04 to 0.06 g.—totalling 1,200 to 1,800 mg.—were given; this approximates the standard accepted curative dosage for conventional intensive therapy—i.e., 20 to 30 mg. per kg. of body weight (Eagle and Hogan, 1943). At first these were also given in divided courses of ten with rest periods; this has now been modified to consecutive doses.

It is a dictum that the longer an estimated arsenical dosage can be spread the less are the toxic effects, so the single daily injection was decided on in preference to the multiple daily injection intensive method, so as to spread the dosage. An early cure with the least possible toxic reaction and minimum dosage is constantly in mind. Again we would like to repeat that these dosages are subject to future modification, depending on follow-up results and toxic effects, but they form a basis for trial relative to the described categories. All patients have been treated as hospital in-patients. Bismuth has not been given.

Reactions

The only serious reaction that has occurred so far has been one case of agranulocytosis.

This developed after a dosage of 1,130 mg. in one of the late primary cases. It was diagnosed within 24 hours of the first symptom—pain in the gums—and treatment with pentnucleotide was started immediately. In three days the blood picture had improved, and after 110 c.c.m. of pentnucleotide recovery was complete. Blood counts done since the patient left hospital have shown that improvement has been maintained. Moore states that this condition is very rare, only 78 cases having been reported up to 1941 in all patients undergoing any form of arsenical treatment for syphilis.

The jaundice figures (11 cases in all) are low compared with the high percentage of cases occurring with the routine neoarsphenamine schedules; only 4 of the cases were discharged to hospital. Jaundice seems to occur as two separate types. One type, of which we had 3 cases, developed between the

eleventh and fourteenth days after starting treatment; it was mild in degree and did not necessarily interfere with the sequence of treatment. The other type (8 cases) developed from the ninth to the twelfth week after the initial injection, when intensive therapy had long been finished. This type was more severe, jaundice occurring about the twelfth week in the routine neoarsphenamine schedules.

In any treatment extending beyond the 10-day period toxicoderma may be expected; but this is not usually a contraindication to subsequent arsenic, although a rest of one month is advisable before further treatment, starting with a very small dose and gradually increasing, bismuth being given meanwhile.

Other toxic manifestations, such as arsenical dermatitis, peripheral neuritis, and toxic encephalopathy, have not occurred. The only headaches were those following lumbar puncture, which is performed on every case before leaving hospital.

Relapses

There were three cases of clinical relapse in our series.

The first was in an early primary case whose relapse was discovered 55 days after completion of treatment. It has already been pointed out that this may have been a misdiagnosis, due to a non-sensitive Q.S.T.S. technique. The second sore occurred on the site of the original chancre, and was preceded by a rise in the Q.S.T.S. from the negative zone. There was no history of re-exposure.

The second case was in a middle primary, and again suggested inadequate initial treatment following on a misdiagnosis, as it may well have been a late primary initially. At relapse the serum was negative, and it was only after a further 10 injections, totalling 560 mg., that the serum was shown to be positive by the introduction of the Kolmer-Wassermann quantitative technique. During two months after his last course of treatment this patient has remained consistently negative, clinically and serologically.

The third case was originally diagnosed as an "early primary," again not on the Kolmer-Wassermann quantitative technique. His serum remained consistently negative for one month before the clinical relapse took place, but became positive during subsequent treatment. His second sore was on the site of his original chancre. This case has been classified as a relapse owing to the second sore being on the site of the original chancre, in spite of the possibilities of reinfection due to the known social and alcoholic habits of the patient.

Reinfections

Since the introduction of intensive therapy, Moore, Shaffar (1943), Schoch and Alexander (1943), and others have laid down new and simpler postulates of reinfection. Judged by these standards we have had three cases of reinfection. The first was in an early primary treated case with a definite history of re-exposure. At the time of reinfection the blood serum was negative. The fresh sore was not on the original site. He was re-treated, and has so far remained negative for over three months. As his consort was an unknown "lady of easy virtue," it was not possible to trace her. The second was in a late primary treated case, marital relations being resumed on the patient's discharge from hospital with sore completely healed and Kolmer-Wassermann negative. He reported 52 days later with a fresh sore, not on the original site. *Sp. pallida* was demonstrated and the Kolmer-Wassermann was negative. Treatment was restarted and his fresh infection was categorized as middle primary. As a matter of added interest, from April 7 to Aug. 12, 1943, this patient received a total of 2,380 mg. of arsenoxide with no ill effects at all. His wife, examined by us, was found to be suffering from active secondary syphilis with a strongly positive Kolmer-Wassermann reaction, and *Sp. pallida* was present in two open lesions of the labia. She had been infected originally by her husband, and had never been examined in spite of requests by us.

The third case was a treated early primary discharged from hospital with a healed sore and a negative blood reaction. He resumed marital relations immediately on discharge from hospital, and reported two months later with multiple sores on the penis—not one, however, on the site of the original chancre. His wife had only started initial treatment with bismuth and intramuscular arsenic the day before her husband returned to her. Subsequently examined by us, she had marked ulceration of her cervix, pronounced generalized adenopathy, and a history of rash and sore throat. Owing to treatment which she had subsequently received before we saw her *Sp. pallida* could not be demonstrated. We feel satisfied that these are three clear cases of reinfection.

Laboratory Routine

In all cases the following laboratory routine is carried out

1. Daily urine Ehrlich and albumin tests.
2. Icterus index at beginning and end of treatment, and du treatment if necessary.
3. Complete blood counts at the start of treatment.
4. B.S.R. estimation.
5. C.S.F. examination.
6. Every case diagnosed on the finding of *Sp. pallida*, except cases of early latent syphilis.
7. *Sp. pallida* controlled until "none found."
8. Daily "Q.S.T.S." done in batches of 50 weekly in the laboratory. The Kolmer's published technique (Kolmer and Boern) is done in a laboratory with 400 to 500 sera are tested weekly by both the Kolmer-Wassermann and the Kahn standard. Originally hundreds of control sera were tested with a standard British Wassermann technique in addition. The tests are therefore adequately controlled, hundreds of repeated tests have shown that, although minor variations in sensitivity occur from test to test, the graphs obtained represent—within the limits of the test—the level of syphilitic reaction in the blood.

Table showing an Analysis of Cases

	Type of Case		
	Early	Middle	Late
No. of cases	40	19	41
Average incubation period (days)	27.5	34.9	61.2
Shortest incubation period (days)	8	5	21
Longest incubation period (days)	63	84	112
Average No. days for sore to heal	7.7	7.7	12.2
Primary fever over 99°	5	7	6
Secondary fever over 99°	12	7	15
Toxicoderma	2	—	2
Jaundice	4	4	3
Agranulocytosis	—	—	1
Relapse	2	1	—
Reinfection	2	—	1
Other toxic manifestations	—	—	—

After an average of 20 hours *Sp. pallida* was not found.

It will be noticed that with 0.04, 0.05, or 0.06 g. of mapharside *Sp. pallida* disappeared from the surface lesions in an average of less than 24 hours, thus proving that mapharside removes that organism from surface lesions in a time comparable with 0.45 to 0.6 g. of neoarsphenamine.

Summary and Conclusions

An attempt has been made to present a new conception of "early syphilis" based on the results of the quantitative Kolmer-Wassermann test performed daily on a series of 100 patients undergoing intensive therapy. By this means early syphilis has been recategorized into three distinct groups or types—"early," "middle," and "late primary syphilis."

We look on this recategorization as giving a new and original line of approach to the treatment of early syphilis by intensive therapy. It provides a fair and reliable index of the intensity of the individual patient's infection, thus allowing him the opportunity of a true scheme of treatment—abortive for the early primary, middle primary, and curative for the late primary. The duration of treatment would be 15, 20, or 30 days respectively, with doses of 600 to 900 mg., 900 to 1,200 mg., and 1,200 to 1,800 mg., depending on body weight. That all these groups should be treated with the same fixed predetermined dosage we feel to be unscientific. "dosage-spread" with the longer time-factor should surely be the toxic effects as recorded by results of the intensive therapy standard doses now in general use, and it should be a great help in removing the menace of encephalopathy, which is always lurking in this work. By means of intensive therapy the problem of continuity of routine treatment schedules in the Services owing to the exigencies of war would be overcome, as interrupted schedules with the resulting drop in percentage of cures, are greatly to the detriment of patient and Service alike.

A warning is not out of place here that intensive therapy should be carried out only in recognized treatment centres: the risk is great on indiscriminate treatment by inexperienced people is great. These treatment centres should have the services of pathologists who are familiar with the Kolmer-Wassermann Q.S.T.S., or some equally reliable sensitive quantitative technique, as it is on pathologist's results that reliance must be placed for accurate diagnosis.

It is realized only too well that at this stage it is far too early to offer anything more than a suggested scheme of diagnosis, treatment, but we hope—and feel—that further investigation of a large number of patients will substantiate our expressed views. These times men are drafted to all parts of the world, where perfect facilities are lacking for blood controls and proper surveillance,

time alone will show whether we are correct in our assumptions. We can only be encouraged by our results of the past eight months. No little purpose will have been served if we have sown the seed for a new line of thought and research on the diagnosis and intensive treatment of early syphilis.

We wish to express our thanks to the Medical Director-General of the Navy, Sir Sheldon Dudley, for permission to carry out this work and for his support. Thanks are also due to Surg. Lieut.-Cmdr. Sloan Miller for all his laboratory co-operation, and to the sick-berth staff for their never-failing help.

ASSESSMENT OF LEVEL OF NUTRITION

REVISED PROCEDURE FOR ESTIMATION OF ANEURIN IN URINE BY THE THIOCHROME TEST

BY

Y. L. WANG, Ph.D.

AND

L. J. HARRIS, Sc.D., D.Sc., Ph.D., F.I.C.

(Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council)

The nutritional status of human subjects in vitamin B₁ can be assessed by examination of the urine before and after test dosing, the procedure being in principle analogous to that introduced previously for determining the level of vitamin C (Harris, Ray, and Ward, 1933; Harris and Ray, 1935) and later for nicotinic acid (Harris and Raymond, 1939). In its original form (Harris and Leong, 1936; Harris, Leong, and Ungley, 1938) the test for vitamin B₁ involved a biological assay of the urine, preferably by the bradycardia method (Birch and Harris, 1934). This has been used by various investigators—e.g., Wright and Baker (1939), Guha and Ahmad (1939). Later the perfecting of the chemical method of estimating vitamin B₁ by the thiochrome reaction (Jansen, 1936) has made possible a great simplification in the routine. In previous papers (Wang and Harris, 1939; Harris and Wang, 1941) we described a suitable technique for the estimation of the aneurin in the specimens of urine by a modified thiochrome test. This has been used satisfactorily by workers in other laboratories (e.g., Slater, 1941; Toverud, 1940). We checked its reliability, by comparison with biological assays, using the bradycardia technique, in several series of comparisons; and the agreement was found to be satisfactory (Wang and Harris, 1939; Harris and Wang, 1941).

Given a little experience, the method is found to work smoothly with nearly all specimens of urine; in rare instances, however, samples may be encountered that give an abnormally whitish-green blank and a dark-blue fluorescence on oxidation, which may make it tiresome to effect a satisfactory matching. To overcome this objection we tried treatment of the urine with H₂O₂, a reagent which had been previously employed by McFarlane and Chapman (1941) in estimating aneurin in green feeding-stuffs. This addition of H₂O₂ reduces the blank considerably and renders the final matching very easy even in the most troublesome specimens of urine (Wang and Harris, 1942). The treatment of the urine with the H₂O₂ does not cause any destruction of thiochrome and presents a distinct advantage, and we now use it in all our routine estimations of aneurin. The method is so simple and rapid to carry out

that it may be employed conveniently in regular clinical tests. For this reason it seems worth while to put together here the working instructions for the modified procedure, incorporating the foregoing and several other small improvements (Wang and Harris, 1942).

Method

1. *Preliminary Washing with Isobutanol*.—Measure 5 ml. of urine into a 15-ml. centrifuge tube, add a drop of concentrated HCl, and shake for one minute with an equal volume of H₂O-saturated isobutanol (redistilled). Centrifuge, discard the isobutanol (top) layer, and note the volume of the aqueous layer.

2. *Oxidation of Aneurin and Extraction of Thiochrome*.—Pipette two 1-ml. aliquots of the washed urine into two 25-ml. glass-stoppered cylinders marked A ("unknown") and B ("blank"). Into a third cylinder, marked C ("control"), introduce 1 ml. of a standard solution of aneurin containing 4 µg. per ml. (For urines collected after test dosing, it may be necessary to use a stronger standard—say, 10 µg. instead of 4 µg. On the other hand, with relatively deficient urines, containing little vitamin B₁, 2 ml. of urine may be taken for analysis instead of 1 ml. and added to cylinders A and B; in this case another 1 ml. of water should be added to the control (cylinder C) to equalize the conditions.) A stock solution containing 20 µg. of aneurin per ml. in 25% alcoholic N/100 HCl is kept for use in a cold place: the diluted standard should be freshly prepared from this. Add to each cylinder 2 ml. of methanol and mix well. To cylinder A add 1 ml. of 20% NaOH, mix quickly, and follow immediately by a 10% solution of K₃Fe(CN)₆, drop by drop, mixing thoroughly after each addition, until the colour of the K₃Fe(CN)₆ stays for more than 30 seconds. (Usually 2 to 3 drops are sufficient; large excess should be avoided.) Treat cylinder C in exactly the same way. To cylinder B, the "blank," add 1 ml. of 20% NaOH, but no K₃Fe(CN)₆. Now add 3 drops of 30% H₂O₂ to all three cylinders (if the urine gives an exceptionally high blank more H₂O₂ can be used). Mix well and allow to stand for half a minute. Then add 1 ml. of H₂O to each, followed by 10 ml. of redistilled isobutanol (if H₂O-saturated isobutanol is used the addition of H₂O may be omitted) and shake for 1 minute. Allow the layers to separate, then draw off and discard the bottom aqueous layer. Add 3 ml. of H₂O to each, shake gently for half a minute and again let the layers separate. Pipette off the top layer of isobutanol into three separate dry conical flasks and clarify with 2 ml. of 96% ethanol.

3. *Comparison of Fluorescence*.—Measure 10 ml. of the clear isobutanol extracts of the oxidized unknown A and the "blank" B into separate test-tubes. (These tubes must be of "non-fluorescent" glass, and uniform in diameter. A convenient size is one in which 10 ml. occupies a column of 6 to 7 cm. The bottoms of the tubes should be of the same shape.) Compare the fluorescence in the tubes, holding them in front of a source of ultra-violet light. The u.v. lamp should be enclosed in a case fitted with a Wood's-glass window, and the room in which the comparison takes place should be completely darkened. Incline the tubes at an angle of about 60 degrees to the horizontal and look down the tubes. The bottom of the tubes should rest on a black platform fitted to the Wood's-glass window. Never look for more than a few seconds, since prolonged exposure to the blue colour will temporarily desensitize the eye; but make a quick inspection and decide which tube has the stronger blue fluorescence. Reverse the position of the tubes and look again. By means of a micro-pipette add the standard of thiochrome (from cylinder C) to the "blank" little by little, mixing well after each addition by closing the tube with the thumb and inverting two or three times, until the fluorescence in both tubes is equal. (The thumb should be thoroughly cleaned with soap and water, as traces of grease may introduce considerable fluorescence.) Before the final matching add to the "unknown" an amount of isobutanol equal in volume to that of the standard added to the "blank." For further details concerning matching, including use of colour filters, see Harris and Wang (1941).

4. *Calculation*.—If U is the volume of urine taken for analysis (1 ml. or 2 ml.), v the volume of the standard used for the matching, x the total amount of aneurin (4 µg. or

10 µg.) in the standard solution, and r_1 and r_2 the volume in ml. of the extract before and after the preliminary washing with isobutanol, then the aneurin content of the urine is

$$\frac{xv}{10} \times \frac{r_2}{r_1} \times \frac{1}{U} \text{ µg. per ml.}$$

(= $\frac{4v}{10} \times \frac{r_2}{r_1}$, when, as in usual circumstances, $x=4$ and $U=1$).

5. Interpretation of Results.—Past work has shown that a normal adult male* subject receiving not less than the reputed requirement of vitamin B₁ (300 I.U.=900 µg. of aneurin daily) excretes at least 90 µg. of aneurin daily (Wang and Harris, 1939). The excretion rises with each increase in the intake, rapidly adjusting itself to such changes. On a diet deficient in the vitamin the excretion quickly falls to a steady value of about 60 to 90 µg., where it is maintained for some time (Wang and Yudkin, 1940).

On the basis of observations such as the foregoing, nutritional status may be assessed by measurement of the "resting level of excretion" plus the response to daily test doses. A "resting" excretion of below 90 µg. combined with one or more days' delay before attainment of the plateau of excretion after the daily standard test doses (350 I.U.) can be assumed to indicate an insufficient intake. For further discussion of standards for excretion tests earlier papers from this laboratory may be consulted (e.g., Wang and Harris, 1939; Wang and Yudkin, 1940).

It is perhaps worthy of note that the differentiation between normal and deficient subjects by means of their urinary response is less steeply graded for vitamin B₁ than, for example, for vitamin C, and thus means that saturation tests are somewhat easier for the latter than for the former. Thus, special emphasis has to be laid on the fact that the excretion of aneurin is relatively "labile," adjusting itself fairly rapidly to each change in the intake, as mentioned above. As a result, the "resting level" of excretion may sometimes do little more than reflect the intake during the few days immediately preceding the collection of the urine. With test doses the deficient subject satisfactorily answers to the test by giving less response than the normal subject on at least the first day, or first and second days, of test dosing; yet after a further day or so both deficient and normal will have reached an equal degree of excretion. (With extreme deficiency of long standing the response to test doses may be delayed a little further.) But for vitamin C, in contrast, the deficient subject may give little or no response at all to test doses for a period of some days, and full saturation will not be finally reached (in developed scurvy) until 7 to 10 days: thus the difference between normal and deficient is made more dramatically apparent than for vitamin B₁.

6. Collection of Urine.—If the urine is not to be tested within an hour or two of its being passed it can be preserved by the addition of a few ml. of glacial acetic acid (or HCl) and toluene.

7. Avoidance of Certain Drugs.—It is important that the patient should not take aspirin, quinine, or related drugs for some hours before or during the time of the test, since these may cause the excretion of highly fluorescent substances in the urine and so make an accurate determination of thiochrome impossible.

Summary

Working directions are given for the method of estimating vitamin B₁ in urine in the test for nutritional status, various improvements in technique being incorporated.

* The minimal level of excretion by females may possibly be slightly lower (cf. Toverud, 1940; Robinson *et al.*, 1940). Precise figures for children, and the more detailed standards for varying intermediate degrees of deficiency, such as have now been worked out for vitamin C (Harris, 1943), still remain to be filled in.

LOCAL ORAL MEDICATION WITH SULPHANILAMIDE IN LOZENGE FORM*

BY

PERCY GARSON, M.D.

Captain, Medical Corps, Army of the United States,
Fort Francis E. Warren, Wyoming

The local application of sulphonamides has been the subject of much interest lately, and this method of treating oral lesions is attracting attention, though a report on the use of sulph anilamide following dental extractions was noted several years back in the *Journal of the Canadian Dental Association*. The oral cavity may be a valuable site for absorption of drugs and particularly in the case of oral lesions, should not cause much surprise. The rich vascular bed of the buccal mucosa is readily available, as witness the immediate relief of substernal pain in angina pectoris after the use of a tablet of nitroglycerin sublingually. Intranasal application of drugs also has its advocates. Cattell (1943) points out "that no outstanding new discoveries in the field of sulphonamide therapy have occurred during the past year, but that, on the other hand, the period has been one of continual progress in the application of the sulphonamides."

It was a search for a suitable means of local oral application and absorption of the drug that prompted me, with the advice of sulph anilamide in 1937, to use it in a vehicle that would permit its slow release in the oral cavity and by direct contact promote local healing and defence against such organisms as are inhibited or destroyed by it. Then, as now, the mechanism of action of the drug cannot be regarded as fully settled, but justification for its application need not await complete elucidation of a *modus operandi*. The present report is based on the results of the direct application of sulph anilamide in lozenge specifically for the purpose of testing its efficacy in cases of acute follicular tonsillitis, the aetiological agent being *Str. haemolyticus*, common at Fort Francis E. Warren, and the subject of much concern to all.

The manner of sulph anilamide administration as practised to-day calls for large doses of the drug—some 7 to 9 g. daily—for therapeutic effect upon a small area on the tonsillar adjacent pharyngeal wall. Other tissues resent playing host to the drug by producing an added lesion at times more disastrous than the original condition. Stated in other words, an attempt was made to reverse the order of mass saturation preceding local therapeutics by a maximal local effect with a minimal blood concentration of the drug.

The vehicles used at the time were chicle (chewing gum) and lozenge. The lozenge proved the more satisfactory means. It could be held in the mouth for a period up to 45 minutes was palatable, and liberation of the drug was slow and uniform. Several lozenges could be used daily, and no disturbing chewing manipulations were required. It was satisfactory both for children and for adults. A lozenge weighing 2 g. and containing 0.065 g. of sulph anilamide proved best suited for the treatment. Observations made at the time on mucous staining, using prontosil and methylene blue in chicle or chocolate, agree with those of Arnett (1943).

The present study is a resumption of the above, though on a much larger scale and under better-controlled conditions. It is intended as a preliminary report, for it would have been more satisfactory had the work been carried through the entire winter season. The incidence of upper respiratory infection is as high during March as in any of the preceding months and it is felt that enough clinical data have been obtained to warrant further investigation at a future date.

The increase in upper respiratory infections is an accompaniment of the expanding army. For the time being, fortunately the diseases are mild, though at times of epidemic proportions. Nevertheless, they incapacitate fairly large numbers of arrivals during their basic training period. This is inevitable owing to the close contact of the men, hence the rapid passage of infection from one individual to another. The problem

* This study was made possible through the assistance and operation of Col. D. W. McEnery, post surgeon, Fort Francis Warren, Wyoming.

keenly recognized as an acute one, and attempts at control are in formation (*Army Medical Bulletin*, 1942) even preceding obilization.

Therapeutics

Patients sent to the main hospital received lozenges, those the Station Hospital Annexe had routine therapy consisting aspirin, codeine, fluids, and gargles. Ward records of both situations were compared. At the main hospital, for purposes this study, any non-follicular red throat was regarded as fluenza. It is impossible consistently to separate influenza on non-follicular tonsillitis. Acute tonsillitis, as defined byecil (1941), "is an acute inflammation of the palatine or ucial tonsils, but in nearly all cases the other lymphatic tissues this region are involved. The tonsils are increased in size id hyperaemic. Many cheesy spots project from the crypts, false membranous exudate may be present in other cases id a similar picture present in adjacent lymphoid tissue." This the type of tonsillitis that is so common in this region. Throat ulture of 24 cases on admission showed 22 to be positive for *r. haemolyticus*.

Each patient was given eight lozenges to take—one each ur between 8 and 11 a.m., one at 4 p.m.; two after the eming meal, and the last just before bedtime. The last dose considered important, as the residual sulphanilamide during eep is less subject to removal than at any other time. Fluids id food were forbidden between meals, as they would wash at the sulphanilamide present in the saliva and adherent to e tonsils and pharyngeal mucosa. The patient was encouraged o take fluids at meal-times. When the morning temperature ached normal, even though the previous evening temperature as 99°, and if the patient felt well, he was sent to quarters ith a two-day supply of lozenges—six daily—and was given ght duty for two days. The reason for the early discharge as based on the theory that if the drug was effective in the ospital it would respond in the same manner in quarters. luids were restricted, and further exposures, as entailed in etting out of bed for gargles or fluids several times a day, ere avoided. Blood sulphanilamide estimations on several ases recorded infinitesimal quantities.

Eighty-six cases of tonsillitis thus treated spent on an average .6 days in hospital; 69 treated influenza cases averaged 2.4 ays in hospital. Ten cases receiving a full systemic dosage f sulphonamides during this period were not considered in ulating the statistics. Only 7% of admissions received the rug in full doses. At the Station Hospital Annexe during the onth of March 41 tonsillitis cases averaged 5.1 days in ospital. The average in 71 influenza cases was 5.7 days.

* H.D. = Hospital days.

Many cases at the Station Hospital Annexe had a normal emperature for one and two days before discharge. No riticism of such routine therapy is intended. However, the omparison revealed itself as the work proceeded. If it is ossible to reduce the average stay in hospital to 2.6 days by local oral therapy a considerable saving of beds is made. The esults obtained at the three dispensaries are in accord with hose at the hospital. The opinions of the dispensary medical officers are uniform, and may be summarized as follows:

1. 50% of the usual hospital cases are now referred direct to quarters.

2. There is a fall of temperature to near normal in 24 to 48 hours.

3. Many cases that show the spotted throat and a normal temperature are aborted by use of the lozenge—i.e., no subsequent rise of temperature occurs.

4. There is rapid alleviation of pain and soreness of throat.

5. The dispensary medical officers feel that the lozenge therapy avoids the frequent necessity for walking to and from wash-rooms that gargles and fluids entail at the barracks, and that these interruptions of bed-rest are done away with entirely.

One immediate effect noticed at hospital and dispensary was the relief of throat pain, which may occur within two hours. This relief was so striking that lozenges containing 3 gr. were supplied to the dental clinics for use in cases of multiple extraction and badly healing wounds. Thus far, not enough material has been gathered to express an opinion with regard to their usefulness for the last-mentioned purpose.

As shown in Table I, 44% of tonsillitis patients and 62% of influenza patients were discharged with normal temperatures within 48 hours. At the Station Hospital Annexe only 2% of all patients were discharged during the same period; in terms of hospital days, 131 to 4—a saving of 127 hospital days. No tonsillitis patients in February were discharged within 48 hours. Only 7% of the total hospital patients for March received sulphanilamide in the usual massive systemic dosage, against 30% at the annexe. It is understood that patients admitted to the hospital were at least moderately ill, with temperature as a rule above 100°.

Prophylaxis

The companies used for prophylactic treatment were composed of new men beginning their basic training. Lozenges were taken at 9 a.m., 10.30 a.m., 1.30 p.m., and at bedtime. Fluids were restricted. In order to avoid carrying over cases in process of development the first three days of administration were not included in the statistics. The lozenges were continued for another fourteen days, each company being examined every morning, with the following results:

Co. K, 240 men, examined by Lieut. J. A. Moore; 100 receiving lozenges developed one case of tonsillitis, or 1% incidence; 140 controls showed 14 cases, or 10%.

Co. F, 167 men, all receiving lozenges, showed 3 cases, or 1.8%.

Co. D, 110 men, 55 receiving lozenges, showed 2 cases, or 3.6%; 55 controls showed 10 cases, or 18%.

Co. G, 257 men, all controls, produced 21 cases, or 8%.

Of 24 throat cultures in Co. F, six were positive for *Str. haemolyticus*, while of 24 throat cultures in Co. G 9 were positive for *Str. haemolyticus*. Blood determinations of the drug on all specimens analysed were recorded as too low for reading.

TABLE II.—Results of Prophylaxis

		Tonsillitis		Influenza	
		Cases	%	Cases	%
Co. K	.. { Treated, 100	1	1	14	14
	.. { Controls, 140	14	10	28	20
Co. F	.. { Treated, 167	3	1.8	13	7.7
	.. { Controls, 55	2	3.6	8	14
Co. D	.. { Treated, 55	10	18	10	18
	.. { Controls, 257	21	8	27	10

Owing to a temporary failure in production the supply of lozenges was reduced in the case of Co. F for two days of the experimental period, and none was administered to all companies on the tenth day of the fourteen-day period.

Discussion

Many pertinent questions can be raised regarding this mode of therapy. The saliva drug content was not estimated, as it would not prove the case one way or the other. Arnett (1943) reports that the salivary sulphadiazine level ranged from 33 to 96 mg. per 100 c.cm. of saliva from chewing 0.3 g. of that drug in paraffin for a period of two hours. As noted previously, blood sulphanilamide levels with lozenges being too low to read, one must infer that a local oral effect is responsible for the results. The amount of the drug—0.065 g.—present in the lozenge, spaced at intervals of an hour, can conceivably produce a bacteriostatic action, particularly in persons of good health. No attempt is made to free the oral cavity of *Str. haemolyticus*. Several questions thus arise. After the initial

two weeks of prophylactic therapy, what is the subsequent course? This remains to be answered, though the companies treated are to be followed up while at Fort Warren. Should a longer period than two weeks be tried? Is there a danger of creating a "mass-sulphanilamide-fast organism?" Such a possibility, particularly with the pneumococcus, *in vitro* and *in vivo*, has been indicated in a recent report of Schmidt, Sesler, and Deltwiler of Cincinnati, working with mice. Are there intraseasonal variations that may alter the figures offered in this report?

Summary

The incorporation of sulphanilamide in a lozenge offers a means of prolonged medication for such lesions of the mouth and pharynx as are amenable to treatment with the drug.

The results obtained in several hundred cases treated therapeutically and prophylactically indicate that this mode of sulphonamide medication shows promise.

I am indebted to Capt. Paul Schneider, Lieut. Leo Weyerich, Lieut. Walter Schwebel, and Lieut. James Moore for valuable assistance in formulating the statistical data and in observation of the patients treated therapeutically in the dispensaries. Capt. A. Walter Ecklund of the hospital laboratory kindly performed the laboratory work involved in this study.

adolescent males receives little emphasis in current textbook and the routine examination of recruits throughout the country must have revealed a considerable number of similar cases the following brief clinical report is presented with a view to drawing attention to the condition, which may be more common than is realized.

In each case the anaemia was first noticed in early or middle childhood. Apart from Case 4, the mildest of the series, there is no history of serious illness. None gave a history of haemorrhage, bleeding piles, or jaundice. No family history of anaemia or jaundice was elicited. All the patients had lived a normal life, enjoying the usual boyhood activities and were following occupations normal to their age without difficulty. Their pallor had been accepted as their natural complexion, and in most cases had not prompted them to seek medical advice. Patient No. 9 (aged 45) did not seek advice on account of his anaemia, which he regarded as trivial and incurable. He had lived an active life as an engineer and was in good general health. His history indicates the benign course of the untreated condition. This man showed good general development, but some of the youths looked small and immature for their age. The majority had not started to shave. None of them were aware of any symptoms of ill health apart from slight breathlessness in the most severe cases. All professed to having received an adequate pre-war diet including plenty of meat, vegetables, and fruit. Their post-war diet appeared to be that of the population at large.

On physical examination all the youths had a smooth pale skin with no evidence of jaundice. In four cases the tongue was noted to be smooth; in the remainder its appearance was normal. In nearly all the cases an apical systolic murmur of haemic origin was present. The spleen was just palpable in four cases, and in one, the most severe, was enlarged two fingerbreadths below the costal margin. Four cases showed spoon nails. In one of these the nails were normal and healthy after eleven months' treatment with iron. All but one (Case 10) showed evidence of deficient gastric acidity—complete achlorhydria in 5 cases and marked hypochlorhydria in 4. Table I gives the ages of the patients and the blood counts. Before treatment typical microcytes and ring cells were present and there was considerable anisocytosis with some poikilocytes. Case 5 was the most severe, and showed an unusual number of macrocytes—possibly a response by the marrow to the marked lack of iron. There was no direct evidence of haemolysis, since no case before treatment showed any reticu-

HYPOCHROMIC ANAEMIA IN ADOLESCENT MALES

BY

M. L. THOMSON, M.D., M.R.C.P.

Honorary Assistant Physician, Salford Royal Hospital

Nine cases of hypochromic anaemia in adolescent males have been referred to me by military medical boards in Manchester during the past two years. Their ages range from 17 to 19, and they present a striking similarity in their clinical and haematological features. A tenth case, that of a man aged 45, belongs to the same group and indicates the later course of the condition in the absence of efficient treatment. Detailed observation was hampered by the men's unwillingness to lose work by attending for investigation and review. It has been

possible, however, to note the effect of treatment in seven of the ten cases. These seven cases all responded fully to adequate treatment with iron. No obvious cause was elicited, and to term the condition "idiopathic" is merely to admit ignorance of their origin. Since this type of anaemia in

locyte increase or excess of urobilin in the urine. The serum bilirubin was at the lower limit of normality. The red cell fragility to saline was normal.

Where treatment could be observed all seven cases responded to iron by mouth (Table I). When we were able to undertake

treatment personally two fersolaté tablets were given thrice daily till a normal count was attained. In Table II the details of the gastric analysis are given.

TABLE II.—Fractional Test Meals. (Cases 1, 6, 7, 8, and 9 showed complete achlorhydria)

Case		Specimens (hours)														
		Fasting	1	1 1/2	2	2 1/2	3	3 1/2	4	4 1/2	5	5 1/2	6	6 1/2	7	7 1/2

HCl = Free HCl N/10 NaOH (% HCl).
T.A. = Total acidity.

It is of practical importance to determine whether a maintenance dose of iron is necessary when the anaemia has been overcome. These cases have not been observed long enough to determine this point. Patient No. 1 had received no treatment for four months previous to his second examination, when his haemoglobin was 110%. Patient No. 2 had received no treatment for six months previous to his last blood count. During this period the haemoglobin was maintained at a high level (Table I).

Discussion

It is not the purpose of this brief clinical report to discuss the many problems of iron metabolism and its relation to hypochromic anaemia. One or two points are worth emphasis. (a) Overt blood loss appears to play no part in the causation of the anaemias. (b) Careful inquiry into the diet gave no grounds for supposing that lack of dietetic iron is responsible for the anaemia. In general these men were particularly fond of the iron-rich foods—possibly a compensatory phenomenon. (c) The high incidence of hypochromic anaemia in the first few years of life and its comparative rarity in school-children suggest that in the present cases there is a specific deficiency. (d) The high incidence of defective gastric acidity suggests a connexion between gastric deficiency and the anaemia.

Summary

A brief clinical report is made of 10 cases of hypochromic anaemia of undetermined aetiology occurring in males. Nine of the cases were revealed by routine examination of adolescent recruits.

Medical Memoranda

Dehydration Fever

Cases of dehydration fever in the newborn are fairly common, but the following case is, I think, almost unique on account of the extreme degree of hyperpyrexia.

Last December I was summoned to attend a baby 3 days old which had been reported by the nurse in charge to have a temperature of 110° F. On arriving at the nursing home I found the infant in a state of extreme prostration; the pulse was weak and uncountable, and the rectal temperature was then 108.4°. This was checked by two thermometers. The child's face and body were almost lilac in colour, the tongue stiff and dry, the lips and mucous surfaces hot, red, and parched.

It was immediately plunged into a tepid bath and after some minutes glucose and saline were run into the rectum (the child being unable to suck). In half an hour the temperature had dropped to 102.4°, and in two hours it had settled at 100.4° F. The baby was by now breathing quietly, his natural colour was restored, and he was able to suck and swallow easily. He is now, ten months later, a fine specimen both physically and mentally.

I do not know how long such a temperature is compatible with life, nor do I know how long the baby had held it before it was first taken. I do know that an interval of 15 minutes elapsed between the recording of the temperature and the institution of treatment.

Reviews

PRINCIPLES OF ORTHOPAEDIC SURGERY

A Practice of Orthopaedic Surgery. By T. P. McMurray, M.B., M.Ch., F.R.C.S. Ed. Second edition. (Pp. 435; illustrated. 30s.) London: Edward Arnold and Co. 1943.

Prof. T. P. McMurray's well-known textbook of orthopaedic surgery makes a welcome reappearance in a second edition. In his preface to this the author states that, though much of the original text has been rewritten and brought up to date and new illustrations have been added, an effort has been made to keep the book, so far as possible, the same size as before. In this object Prof. McMurray has succeeded admirably, and his book is still, as was the first edition, a handy, concise exposition of the basic principles of orthopaedic surgery intended primarily for the young surgeon and senior student. The subject-matter of the various diseases and deformities is clearly set out on a systematic plan with avoidance of too much confusing detail and theory, and under the sections on treatment only those operative procedures which have, in the author's wide experience, given the most consistently satisfactory results are described.

Differential diagnosis of the various conditions is given due weight, though under this heading mention might perhaps have been made of the now proved value of biopsy examination of the inguinal and iliac lymph nodes in tuberculosis of the knee and hip joints respectively. Prolapse of the nucleus pulposus of an intervertebral disc also has acquired so much notoriety of recent years that one wonders it did not find a place in a revised edition of this textbook as a cause of spinal nerve root irritation leading to sciatica, and especially to sciatic and alternating sciatic scoliosis. These, however, are small matters which do not detract at all from the value of an excellent and practical treatise on the principles of orthopaedic surgery in the direct tradition of the great Master of Orthopaedics, to whom the book is dedicated. The young orthopaedic surgeon who bases his practice on the lines so ably laid down for him in this book will certainly have no cause to regret it.

PROCTOLOGY FOR THE G.P.

Proctology for the General Practitioner. By Frederick C. Smith, M.D., M.Sc. Second revised edition. (Pp. 466; illustrated. 54.50.) Philadelphia: F. A. Davis Company.

The most useful chapters in this book, from the point of view of the general practitioner, are those on ano-rectal symptomatology and methods of diagnosis. The author rightly attaches much importance to obtaining a careful history in cases with even minor rectal complaints, and complete routine examination is necessary if mistaken or incomplete diagnoses are to be avoided. The chapters on anaesthesia, parasites, venereal diseases, and constipation are reliable and full of information. The author uses local anaesthesia for minor procedures such as ablation of anal crypts or excision of papillae and thrombotic external piles, but prefers general anaesthesia for what he calls the major rectal operations, such as haemorrhoidectomy, cure of fistula, or excision of pilonidal sinuses. Chapter IX, on anal pruritus, should prove to be particularly helpful to practitioners, and we note that in the author's experience x rays and ultra-violet light have not given good results. He questions the value of undercutting operations. We might point out that the story of the doctor suffering from pruritus who had to devise a gadget to restrain his hands, which is related on page 235, is repeated almost verbatim on page 241.

For cure of anal fissures the only methods described are division of the sphincter and excision; there is no mention of local treatment for recent superficial fissures. Many of the surgical procedures described cannot be recommended and are contrary to the accepted practice in this country. For instance, five methods of haemorrhoidectomy are described, preference being given to the clamp and cautery operation. In particular we cannot support the author's rather loose description of ano-rectal abscesses and his advice that at the primary operation

ments with regard to the Thames and Lee are working satisfactorily and should not be disturbed. The formation of 29 new Boards is envisaged, which with those of the Thames and Lee will take over the duties at present exercised by more than 1,600. It is hoped that with larger financial resources the new Boards would be able to maintain full-time scientific and technical staffs to make expert observations and give expert advice; they should be assisted by a central research organization such as that under the Water Pollution Research Board of the Department of Scientific and Industrial Research. These proposals represent a great advance in the management of our rivers, and it is to be hoped that they will be speedily put into force.

MATERNITY SERVICES IN NORTHERN IRELAND

In 1936 the Ministry of Home Affairs in Northern Ireland appointed a committee to examine the organization of maternity services. Prof. R. J. Johnstone was its chairman, and on his death the chair was taken by Prof. C. G. Lowry. The report¹ is dated June, 1939, but its publication bears the date 1943. We are told that the approach of war held it back, and that in the meantime no legislation associated with the report has been introduced. A select committee on public health services is now sitting in Belfast, however, and possibly the problem of maternity services will be freshly reviewed. The Government, with Sir Basil Brooke as the new Prime Minister, is, we are assured, giving earnest consideration to the whole question.

One of the conditions which the committee lays down as essential is the separation of maternity services from Poor Law administration. In Northern Ireland the public midwifery services provide only for the destitute poor. Generally speaking, for the whole population above the status of pauper, midwifery provision in its broader sense is a private matter. Moreover, the services provided for the destitute poor have regard only to the actual confinement. The Boards of Guardians pay such a small salary that the midwife, if she is to earn a living wage, must undertake private practice, with the result that she may be overworked and her non-paying patients may suffer from lack of attention. The average total income of a Poor Law midwife is said to range from £52 to £92 per annum. The question of ante-natal supervision has been tackled systematically only in the city of Belfast, and even there the proportion of women who receive supervision throughout the whole of their pregnancy is small. The committee has no doubt whatever that a high proportion of fatalities in childbirth is the direct result of the lack of such supervision. Strong adverse criticism of the existing system of maternity services was made by the witnesses who appeared before the committee, including the Northern Ireland Branch of the British Medical Association. The committee recommends that the public maternity services be removed entirely from the Poor Law and reorganized under county councils and the corporations of county boroughs; that a Central Midwives Board be set up for Northern Ireland; that a medical superintendent officer of health be appointed for each county to control the entire medical services assumed by the county council, and that in each of the areas the administrative body be required to provide ante-natal and post-natal services, an adequate staff of well-trained and fully paid midwives, a consultant service, institutional facilities, transport, foodstuffs and medicines in necessitous cases, and the disinfection of clothing and bedding. In the opinion of the committee the sum of £180 per annum is the lowest which is likely to attract the type

of woman whom it is desired to see employed as a midwife; in addition to the salary, housing accommodation should be provided, together with an allowance toward uniforms. (The Rushcliffe Committee, which recently reported on midwives' salaries in England and Wales recommended for a district midwife, if she is also a State registered nurse, a salary of £140, rising by increments of £10 to £200, with, in addition, emoluments of a total value of £100. If she is not a State-registered nurse the salary scale should begin at £120 and have its maximum at £190. An essential of the scheme for Northern Ireland would be compulsory attendance at refresher courses for midwives at intervals of two years, and midwives should be compulsorily retired at sixty.

Northern Ireland has had a deplorably high maternal death rate. In 1938 the death rate from puerperal sepsis per 1,000 births was 1.20—itsself a lower figure than has obtained during the previous ten years—and from other puerperal diseases 4.12, comparing with rates for England and Wales for the same year of 0.89 and 2.19 respectively. In Belfast in 1938 the death rate from puerperal disease was 5.25. It is a great pity that the committee's report has been held up for four years, and we hope that no similar delay will take place before its recommendations are brought into effect.

CHAIRMANSHIP OF THE COUNCIL

Mr. H. S. Souttar, who had been Chairman of Council of the B.M.A. since the Aberdeen Meeting in July, 1939 made it known that he would not seek re-election this year and the new Council at its first meeting on Sept. 23 unanimously elected Dr. H. Guy Dain to the chair. In his brief acknowledgment of this well-deserved honour Dr. Dain expressed the Council's sense of obligation to the outgoing Chairman. Mr. Souttar has had no easy task as chief executive officer of the Association during the first four years of the greatest war in history; but his courtesy and good humour never failed him, whether as Chairman of Council, as Chairman of the Central Medical War Committee, or as Chairman of the Medical Planning Commission. An additional service to the profession was his wartime visit to North Africa, Egypt, Iraq, and India as head of a mission sent by the Secretary of State for India at the request of the Government of India, which led to the immediate formation of the Indian Army Medical Corps. The gracing of public ceremonies, for which he is so well fitted, was denied to Mr. Souttar as Chairman of Council; work and care have been his portion. Dr. Dain, with years of experience in leadership behind him, comes to the chair at a critical time, but with the knowledge that he has the confidence of the Association.

SOCIAL WELFARE IN THE U.S.A.

Social welfare in the United States is as earnestly pursued as in Great Britain, and the discussions on health and economic security, industrial relations, public assistance, and family allowances have much the same ring. But on reading more than fifty papers which were presented at a recent conference at New Orleans¹ one is conscious of differences between British and American sociological approach. The Americans are more scientific, more objective, perhaps—if the word is not misunderstood—more business-like in dealing with social problems. Their cases are wonderfully well classified and docketed and supported by statistics. On the other hand, they seem sometimes to

¹ Cmd 219. H.M. Stationery Office, Belfast. (9d.)

¹ *Proceedings of the National Conference of Social Work*. Selected Papers Sixty-ninth Annual Conference, New Orleans. (Pp. 681. 33s. 6d.) New York: Columbia University Press; London: Oxford University Press.

be less aware of human factors and psychology. There is something about the very thoroughness with which social investigation is undertaken which makes us admire and at the same time stand slightly appalled. It is an excellent thing to follow up the men rejected by medical boards for selective army service, to pursue them, even across a continent, with forms and bulletins, with permissions signed in triplicate and witnessed, with interviews and referrals, with the ascertainment of financial data and family history, with reports from doctors, dentists, clinics, and community agencies, until the man must feel that the very "Hound of Heaven" is after him. There is a very good chance (a 64% chance according to the figures for one group) that the man will be rehabilitated—unless in the meantime he be badgered to death. One paper, by I. S. Falk, who is the director of the bureau of research of the Social Security Board at Washington, gives a rather subdued picture of the progress made since a five-point health programme was established by an interdepartmental committee of the Federal Government six years ago. He says that there has been no substantial achievement since then in the way of expansion of public medical services or the development of health insurance. Federal aid to these ends has been made available only for a venereal diseases programme. No State has developed a programme for medical care on an insurance basis or any comprehensive programme of public health services. Hospitals have grown in number, but the increase has been mainly in Government institutions, most of which are not available to the population as a whole, and health and diagnostic centres and clinics and out-patient facilities have not substantially improved since 1937-8. An interesting but not too cheerful picture of the United States in its first year of war.

One paper in the collection is by Mr. Malcolm MacDonald, on wartime social services in Britain. Mr. MacDonald paints with a cheerful brush. We wonder how many rescue squads would endorse his remark about air raids that even "when houses get smashed their householders usually escape without a scratch. They emerge hale and remarkably hearty, only they suddenly have no roof over their heads." Again, he describes evacuation as if it were a picnic, with everything in the country garden lovely. Perhaps the transatlantic perspective is needed in order to appreciate how shadowless is the landscape of wartime England.

POLIOMYELITIS

The advancement of our knowledge about poliomyelitis has hitherto been retarded by two special difficulties confronting the experimental investigator. In the first place monkeys are the only readily available animals susceptible to virus from human sources, and even they are relatively resistant to infection. Secondly, many of the crude materials which contain virus are so toxic and so heavily contaminated with bacteria that only small doses are tolerated, and they cannot be administered by the most sensitive—intracerebral—route of inoculation. Isolation of virus from the excreta of cases and carriers and from sewage has therefore been largely a matter of chance. A recent paper by Melnick¹ introduces a method of virus concentration and purification which may eliminate the second difficulty. By means of the ultracentrifuge the virus contained in as much as 30 g. of faeces is obtained in a volume of 1 c.cm., the whole of which can be inoculated intracerebrally into a monkey. Comparative titration experiments indicated that the new method is at least 100 times more sensitive than the best of the older methods. If this is substantiated it represents an advance of great

practical importance, because the solution of many outstanding problems depends upon the isolation of virus strains from as many different sources as possible.

The classical conception of poliomyelitis as a disease caused by a single virus, spread by droplet infection, and invading the central nervous system from the nasopharynx via the olfactory bulbs, is no longer wholly tenable. The trend of modern research is to focus more attention on the intestinal tract, both as a portal of entry and as a route of elimination of the virus. Apart from the very frequent reports of isolation from stools, the pattern of virus distribution in a series of fatal cases was considered by Sabin and Ward² to point to the alimentary tract as the primary site of attack and to exonerate the nasal mucosa and saliva from participation in virus multiplication and dissemination. Such a view demands a reasonable hypothesis to replace the droplet infection hypothesis. Direct case-to-case transmission presents no difficulty, but how does the virus survive outside the human body during interepidemic periods and how does it regain access to the human alimentary tract? Trask and Paul³ consider that circumstantial evidence points to some extra-human host in the chain of transmission, and have recorded two instances in which virus was detected in flies collected during epidemics.⁴ Most of the available evidence, however, suggests the mouse or other small rodent as a possible reservoir of infection and intermediate host. The mouse appears to be particularly prone to virus infections of the central nervous system, and the naturally occurring mouse encephalomyelitis bears striking resemblances to human poliomyelitis. Moreover, two human strains of poliomyelitis virus have been successfully adapted to mice. On the other hand, the numerous failures to adapt strains to mice should not be forgotten. Recently Jungeblut and Dalldorf,⁵ by inoculation of hamsters, cotton rats, and mice, have isolated two viruses during an outbreak of poliomyelitis which involved five cases in a sharply circumscribed area: one was from the cord and medulla of a fatal case, the other from a grey house mouse found dead in the house of the same patient. An important question is whether they can be accepted as true poliomyelitis viruses. All the circumstantial evidence favours an affirmative answer, but the authors themselves realize the risks involved in using rodents for virus isolations. Serum neutralization tests indicated definite relationship with monkey poliomyelitis virus, but much closer affinity to the SK murine strain and to Theiler's mouse encephalomyelitis virus. Perhaps the time is fast approaching when we shall regard poliomyelitis as a clinical entity caused by a number of related viruses, differing both in their antigenic structure and in their range of species pathogenicity, much as we now know to be the case with influenza.

FACTITIAL PROCTITIS

Radiotherapy of carcinoma of the cervix uteri has been so successful as to have become more or less standardized in principle, and it is accepted that both intracavitary radium application and external irradiation by x rays are necessary for adequate dosage. But since this dosage has been satisfactorily worked out intestinal injuries have been increasingly recognized. A mild acute proctitis is often produced, but it subsides soon after the completion of the irradiation, and the later irradiation reactions—to which the term "factitial proctitis" has been given by Randall and Buie⁶—are unrelated to it. The incidence of these late

¹ *J. exp. Med.*, 1941, 73, 771.

² *Amer. J. publ. Hlth.*, 1941, 31, 239.

³ *Science*, 1941, 84, 395.

⁴ *Amer. J. publ. Hlth.*, 1943, 33, 169.

⁵ *Amer. J. Obstet. Gynec.*, 1943, 45, 505.

intestinal injuries is between 3 and 5%, but Aldridge⁷ reports intestinal strictures in 16% of 142 cases. There are two main types of injury, aptly termed by Todd⁸ intrinsic and extrinsic: the former is limited to the rectum and may resemble an operable carcinoma of the rectum, while the latter presents a massive perirectal fibrosis which may be mistaken for a widespread pelvic recurrence or for an inoperable carcinoma of the rectum. In both types the rectal ulceration occurs on the anterior wall at the level of the cervix and has a radionecrotic appearance, so that it would be natural to regard it as due to an overdose of radiation. But in none of these three reports was there any obvious relation between dosage factors and late intestinal injuries, nor were they associated with the degree of malignant involvement of the parametria nor with the presence of pelvic inflammation. The suggestion made by Hurdon⁹ that the lesions are due to endarteritis, and related to the blood supply rather than to the dosage, has been supported by Todd's demonstration that the rectal ulceration occurs in the anastomotic area where an endarteritis would be expected to have maximum effect, and that the perirectal fibrosis—"frozen pelvis"—is almost confined to the posterior segment where the blood supply is poorest. On the other hand, Corscaden,¹⁰ in reporting 15 cases of intestinal injury, had had no further cases since increasing the over-all time of irradiation from 3 to 6 weeks. The ulcer confined to the rectum heals as a rule spontaneously over a period of months, generally without any stenosis and indeed without any residual lesion at all. When there is also perirectal fibrosis, however, colostomy is needed in about one-third of the cases for either stenosis or haemorrhage. Pain is also a prominent symptom, for which Todd advises presacral sympathectomy, because colostomy alone often failed to relieve it. The fatality rate of these late injuries is fortunately small, and one may conclude that the risk of factitial proctitis is a justifiable one to take in attempting to cure cancer.

The incidence of late radiation injuries in the urinary tract is difficult to assess, because similar changes are so often the result of the malignant process itself. Indeed, Ewing¹¹ stated that the natural termination of most cases of uterine cancer is through uraemia from occlusion of the ureters. Hayllar¹² points out that ureteric obstruction whether due to late radiation fibrosis or to malignant invasion of the peri-ureteral lymphatics with subsequent replacement fibrosis, may occur in patients without recurrence of cancer, and that ureteral drainage and monthly dilatation will permit their survival in comfort for long periods, thus adding a further small percentage to the statistical survival rates.

TOXIC HAZARD OF BERYLLIUM

Although beryllium, which belongs to the same chemical family as magnesium and calcium, was discovered in 1797, it was very little known before 1916, and has become of prime economic importance only since 1940, chiefly because of its copper alloy, which is extremely resistant to fatigue and corrosion. The principal ore is beryl, a beryllium aluminium silicate, which is widely distributed although rarely in large deposits. Extraction of beryllium from this ore is difficult, necessitating high temperatures and fusion methods, and it is during these extraction processes, especially the fusion of crushed beryl with sodium silicofluoride, that the industrial toxic hazard of beryllium arises. From time to time reports of severe poisoning of workers in beryllium foundries have appeared, but whether the

effects were due to the fumes or dust of beryllium or beryllium fluoride, or to other fluorides evolved during the fusion process, has never been definitely agreed.

Among the manifestations of beryllium poisoning have been skin irritation, hepatonephritis, beryllium rickets, and "berylliosis"—the term given to the type of lung damage caused by inhalation of the dust or fumes of beryllium compounds. This condition has recently been observed in America¹ in three workmen employed in extraction of beryllium oxide, and has been described as a "chemical pneumonia." Although no fluoride was used in this particular process, the symptoms and x-ray findings corresponded closely with a similar disease described by Gelman² as bronchio-alveolitis or peribronchio-alveolitis, and believed by him to be due to fluorine separated in the lungs from beryllium oxyfluoride. The characteristic symptoms and physical findings were dyspnoea, cough with occasional blood-tinged sputum, low-grade fever, shallow rapid respiration, mild to moderate cyanosis, and fine crepitant rales throughout the lower half of both lungs. A radiograph about three weeks after the onset of symptoms showed diffuse haziness of both lungs, prominence of peribronchial markings, soft irregular areas of infiltration, and discrete small nodules. All three patients recovered, the x-ray picture being then normal. Since an identical "chemical pneumonia" of undetermined aetiology was also observed in a rayon factory worker, it is suggested that beryllium was not necessarily the direct causal factor in the three cases described.

A still more recent investigation³ of the action of beryllium on experimental animals appears to confirm the view that it is not itself inherently toxic. Very little beryllium was stored in the tissues of animals which were given large amounts by the mouth, by inhalation, or by intraperitoneal injection, and there was no evidence of "beryllium rickets." Nevertheless, exposure of guinea-pigs and rats to the fumes from the electrolysis of molten fluorides containing beryllium fluoride or oxyfluoride showed that these fumes were decidedly toxic. No specific pneumonitis occurred, but it was believed that the hydrolysis products of the compound were so toxic that the animals died before pulmonary damage could develop. It appears probable, therefore, that the industrial hazard of beryllium arises from the toxicity of its fluoride or oxyfluoride or from the hydrolysis products of other salts rather than from beryllium itself, and that these effects must be taken into consideration in any measures for safeguarding the conditions of preparation of beryllium or its alloys.

The Harveian Oration will be delivered before the Royal College of Physicians of London by Dr. W. E. Hume on Monday, Oct. 18, at 2.30 p.m., at the College, Pall Mall East.

The British Council film, "Surgery in Chest Disease," which was the subject of an annotation in our issue of Sept. 25 (p. 297), will be given a second showing at the Curzon Cinema on Monday, Oct. 11, at 5 p.m. Some seats are still available, and those wishing to take advantage of them should apply to the Film Department, the British Council, 3, Hanover Street, London, W.1. The British Council has very kindly agreed, when prints are ready, to loan the film to B.M.A. Branches and Divisions. It is a 35-mm. sound film, and takes just under 40 minutes to run. We feel sure that many Branches and Divisions will seize the opportunity to see this film of exceptional merit and interest, which has been praised highly by the leading film critics of the country.

NEUROTIC AND PSYCHIATRIC STATES AS
CAUSES OF INABILITY TO WORK
IN ENGLAND, 1940-1

BY

HOWARD E. COLLIER, M.D., Ch.B.

This study was undertaken in the hope that the statistical material available to me in my capacity as a medical referee to a large industrial insurance society might throw some light on the following points: (1) the actual incidence of neurotic and psychiatric illness in this country at the present time; (2) the relative importance of the "nervous factor" in causing delay in recovery from illness; (3) the probable amount of definitely psychiatric illness present in the community for which specialist psychiatric "treatment" should be provided in a reorganized medical profession.

The Material

With these general objects in view and after a preliminary discussion with Dr. Russell Fraser, who is engaged on the same general problem on behalf of the Medical Research Council, large samples of records made at the time of examination by three medical referees (working independently) for a large benevolent and approved society in the Midland area during the years 1940 and 1941 were analysed. I personally interviewed and recorded the notes of about one-third of the cases; the rest were seen and recorded by colleagues, without whose work the present study could not have been carried out. Series of 500 record cards were taken in alphabetical order from the files of both male and female patients for each of the two years under review—making 2,000 cases in all.

The Analysis

All the clinical notes were read by me and each case was allocated to one of the three clinical groups. (All doubtful cases were classed as physical.) In consultation with Dr. Russell Fraser the following categories were selected.

Group I.—Physical diseases uncomplicated by evident neurosis.

Group II.—(a) Physical diseases complicated by "neurotic" symptoms of such a kind or degree as to make it clear that the mental element in the case was significant as a cause of the disability or its undue prolongation. **(b)** Minor or secondary neurosis—i.e., cases in which psychiatric disorder was the main cause of the disability, though often a feature complicating other illness, and treatment was probably simple.

Group III.—Cases of frankly psychiatric origin: that is to say, major psychiatric disability—viz., the psychoses, and also cases probably requiring expert psychiatric attention not within the competence of the ordinary practitioner.

TABLE I.—Nervous and Psychiatric Illness (Rate per 1,000 Cases in Brackets)

Description of Material	"Population"	Group II: Neurotic or Psycho- somatic	Group III: "Major" Neurosis or Psychiatric	Combined Groups II and III
(1) Cases of "ordinary sickness" seen by medical referees	1,693	272 (160)	202 (119)	474 (280)
i) Analysis according to sex:				
(a) Males	809	112 (140)	87 (100)	199 (246)
(b) Females	884	160 (190)	115 (129)	275 (320)
(c) 1940 males only ..	410	63 (153)	47 (110)	110 (260)
(d) 1941	399	49 (120)	40 (100)	89 (220)
j) Analysis according to age (if recorded):				
(a) Males under 30 years ..	176	24 (136)	18 (102)	42 (239)
" over 30 years ..	624	77 (123)	63 (100)	140 (224)
(b) Females under 30 years ..	450	84 (185)	68 (142)	152 (317)
" over 30 years ..	404	76 (188)	47 (113)	123 (304)
(c) Males and females:				
Under 30 years ..	656	103 (165)	86 (131)	194 (295)
Over 30 years ..	1,028	153 (159)	110 (107)	263 (255)
k) Analysis according to marital state (females only):				
(a) All single women ..	438	89 (203)	72 (165)	161 (369)
(b) All married women ..	446	71 (160)	43 (96)	114 (256)
(c) Single women under 30 years ..	282	55 (195)	48 (170)	103 (366)
Single women over 30 years ..	156	34 (208)	24 (154)	58 (378)
Married women under 30 years ..	198	29 (147)	20 (101)	49 (246)
Married women over 30 years ..	248	42 (168)	23 (93)	65 (262)
(d) Age in 1940 and 1941:				
1940 All single women	235	51 (217)	31 (134)	82 (348)
1941	213	38 (173)	41 (193)	79 (370)
1940 All married women	207	39 (185)	24 (116)	63 (304)
1941	239	32 (133)	19 (80)	51 (214)

TABLE II.—Distribution of "Population" in the Various "Social Classes" (Males only)

	Social Class i: Managers	Social Class ii: Under- managers	Social Class iii: Skilled Workers	Social Class iv: Semi- skilled	Social Class v: Unskilled
(5) Occupation recorded in 915 cases	3 (3.4)	51 (56)	460 (505)	303 (338)	93 (103 per 1,000 examined)
(6) Distribution in standard population*: E. and W. Census, 1951	— (25)	— (142)	— (499)	— (181)	— (167 per 1,000 employed)
(7) Incidence of "nervous disease" according to "social class" (Total, 915)†	1 (—)	11 (—)	83 (183)	65 (200)	15 (160) Total 175 (181 per 1,000 examined)

* All occupied and retired civilian males.

† For this analysis accidents were included to enable a sufficient number of cases to be obtained for analysis. Occupation was not always recorded in the notes made by the referees.

The material was further analysed from a variety of points of view: into the *age groups* in respect of Groups I, II, and III for both male and female cases; in respect of *married or single state* with regard to the female cases only; into *occupation groups* in respect of the male cases only. (It is generally recognized that an occupation analysis of women workers does not yield reliable results.)

It was thence possible to allocate all of the male workers (whose occupation had been recorded) to one of the five social classes described by the Registrar-General in his Decennial Report of 1931, and to discover the "general structure" of the population at risk in respect of its economic and occupational conditions. In making this last analysis I used my knowledge of occupations and the names by which workers describe them.

Lastly, by the courtesy of the general secretary of the society some very useful information was obtained concerning the nature of the population at risk, its sex distribution, etc.

The results of these inquiries are summarized in the Tables.

Discussion

The interpretation of these results will depend largely upon the view taken of the degree of artificial selection to which the material is subjected before reaching the medical referee. Something must be said, therefore, concerning the methods and criteria by which the cases are chosen for "reference."

Cases for reference are summoned by experienced non-medical officers of the society: (a) because the period of disability is unduly long having regard to the diagnosis (e.g., a cold might be summoned after 3 weeks, but pneumonia only after 3 months); (b) because of recurrent trivial illness; (c) at the end of 12 months' disablement to ascertain whether the disablement is likely to be permanent; (d) cases of accident, suspected industrial disease, vague diagnosis, etc., to "ascertain liability"; (e) cases in which sick-visitors consider that alternative light employment might be undertaken. There is a definite tendency, therefore, for "neurotic" cases to be summoned, although some of them no doubt return to work rather than appear before the medical referee. No cases that are unable to travel appear before the medical referee.

It will be seen from Table II (item 5) that the membership of the society is chiefly drawn from the skilled and semi-skilled working groups. (The relative incidence of neurosis in the social classes deserves further study.)

The society consists of two sections: (a) the parent society, which is a voluntary benefit society (P), and an approved section, which is a national health approved society (A). A proportion of the members of both sections do not qualify for benefit. These have been excluded from the figures in calculating the population at risk. The two sections of the society (P. and A.) do not differ very greatly in size or sex distribution. The total numbers qualified for benefit (and therefore liable to be summoned to the referee) are 204,674 males and 72,459 females, making a total of over 277,000 members: but of these about 77,000 live too far from the office of the medical referee to be summoned. Hence the *basic population at risk* is about 200,000 persons. It is found that in regard to males, to females, and to the parent and the approved sections, a proportion of *one in three* of the members claim benefit every year. During the year 1940 the society received over 97,000 claims. (In some instances one member may make several claims in one year.) In respect of these 97,000 claims 5,522 persons were summoned to appear before the referee in 1940, and of these nearly 50% returned to work prior to the date of examination. The remainder were seen by the referee.

and constitute the records from which the material studied in this paper has been derived.

Interpretation of Results

The most striking fact about the figures in Table I is their general uniformity and consistency. There was an over-all incidence of 280 cases of all kinds of neurotic disorder in each 1,000 examined. We may conclude, therefore, (1) that about 280 per 1,000 of all cases of unduly prolonged disablement are due to or associated with manifest nervous or psychiatric disease, or that about 280 in every 1,000 disabled persons are likely to experience an *unduly prolonged disablement by reason of "nervous disorders."* (2) In the material surveyed there is a considerably higher incidence of nervous illness among the women than among the men (320:246). It will be noted that this excess is confined chiefly to single women (Table I, item 4) both below and above 30 years of age. (3) Item 7 (Table II) suggests that "social state" is not an important factor in the differential or actual incidence of nervous disorders—at least, in respect of Classes iii, iv, and v. (4) Finally, with all due reserve an attempt may be made to relate the figures to the membership of the society as a whole, and thence perhaps to the community as a whole, since it is improbable that the experience of the community is less favourable than that of a benevolent society of high standing.

Of the patients summoned for examination on account of unduly prolonged illness 50% returned to work before seeing the referees. There are two extreme and opposite assumptions that could be made: first, that in fact the referees saw *all of the cases* whose illnesses were unduly prolonged by "neurosis" and that there was no neurosis among those that returned to work; secondly, that the referees saw *only one-half* of those cases—i.e., only those who did not return to work. In my view it is probable that the truth lies somewhere between these two assumptions. Taking the first assumption, we can estimate minimal, and, taking the second assumption, estimate maximal, rates of the probable incidence of neurotic disorder as a factor in causing unduly prolonged illness in the population.

We know that 5,522 persons were summoned; our analysis shows that 28% of those actually seen were found to be "neurotic." Since the referees saw about 50% of those summoned, we may estimate that at least 14% of the persons summoned were "neurotic"—that is, 770 estimated cases. These cases were derived from a total insured population of about 200,000 persons, male and female. Hence we may estimate that neurosis as a significant factor causing prolonged disablement occurs in 3.8 per 1,000 of the population at risk—the members of the society. Since one member in three claims benefit each year, we may estimate that at least 1.2 per 1,000 of the insured population suffer from disabling neurosis each year. Our study showed also that out of 28 neurotics 12 would be classed by me as "psychiatric," as described above. Hence we estimate that at least 1.5 per 1,000 of the insured population require expert psychiatric help.

If we accept the maximum hypothesis, each one of these rates would be multiplied by two. Thus:

76	per 1,000 insured persons will be disabled by neurosis
24	" " disabled
30	" " will require "expert" psychiatric assistance

I find that during the last 3 years I have sent patients to psychiatric consultants at a rate of about 1 patient per 1,000 persons for whom I am responsible as a doctor.

ADVERTISING PROPRIETARY MEDICINES

The following rules governing the publication of advertisements for proprietary medicines were unanimously adopted at a recent meeting of the Newspaper Proprietors' Association:

1. No advertisement will be accepted by the newspapers represented in the N.P.A. which offers for sale to the public any medicine or treatment which is directly or by implication held out in terms calculated to lead to the belief that the medicine is effective in:

(a) The treatment of Bright's disease, cancer, tuberculosis or consumption, diabetes, epilepsy, fits, locomotor ataxy, cataract, glaucoma, disseminated sclerosis, osteo-arthritis, spinal, cerebral, and venereal diseases, lupus, or paralysis, or for preventing any of those ailments.

(b) For the cure of amenorrhoea, hernia, blindness, rheumatoid arthritis, or any structural or organic ailment of the auditory system.

(c) For procuring the miscarriage of women.

(d) For the treatment of habits associated with sexual indulgence or of any ailment associated with those habits.

2. No advertisement will be accepted from an advertiser who by printed matter, orally, or in his advertisement undertakes:

(a) To diagnose by correspondence diseased conditions or any particular diseased conditions in a human being, or to receive from any person a statement of his or any other person's symptoms of ill-health with a view to advising as to, or providing for, the treatment of such ill-health by correspondence; or

(b) To treat by correspondence any of the ailments specified in Section 1 above.

3. No advertisement will be inserted containing a testimonial other than one limited to the actual views of the writer, or any testimonial given by a doctor other than a recognized British medical practitioner unless it is manifest that the writer is not a British doctor of medicine.

4. No advertisement will be accepted containing illustrations which are distorted or exaggerated in such a manner as to convey false impressions.

5. No advertisement will be accepted which in any way may lead persons to believe that the product recommended emanates from any hospital or official source or is other than a proprietary medicine advertised by a particular manufacturer for the purpose specified, unless the advertising agent submitting the copy declares that the authority of such hospital or official source had been duly obtained.

The secretary of the N.P.A.'s Advertisement Committee informs us that the rules are now in operation in all the London morning, evening, and Sunday newspapers, and all advertisements will, in addition to conforming to these rules, be submitted to medical scrutiny and the product to chemical analysis if it is considered necessary. This is the first time that the national newspapers have unanimously laid down and insisted on a standard of control over statements and claims made in advertisements.

Correspondence

X Rays and the Colon

SIR.—I also was present at the meeting when Sir Arthur Hurst opened a discussion on the functional disorders of colon and uttered a warning—in my opinion a timely one—against placing too much reliance on the help which radiology can give in cases of so-called colon spasm or irritable colon. Surely, most physicians and many radiologists of wide experience will agree that in many of these cases, essentially spasm in their manifestations, the colon may appear normal, when examined by barium meal or enema.

I have had occasion recently to look through my case records of functional colon disorder and find that among the 1200 cases 78 were examined by barium meal and 35 by enema. In the opaque meals evidence of dysfunction, as shown in areas of spasm and of abnormal rates of passage, was found 51 times, and there were 27 normal results. In the 35 enemata 25 were normal and 10 showed some abnormality.

I have only a very limited acquaintance with the method of studying mucosal patterns introduced by Forsell and elaborated by Berg and others. They may give more information, but they are laborious and time-consuming and do not appear to have been generally adopted in this country or the United States as a routine procedure. The clinical picture of colon spasm was put on a sound basis by Howship, Ha White, and Hawkins without the aid of radiology, and, great and essential as its contributions have been and will be to the understanding of alimentary disease, in this particular group of psychosomatic disorders they have not as yet proved conspicuous.—I am, etc.,

Birmingham.

T. L. HARDY.

Psychiatry at the Cross-roads

SIR.—Psychiatry is at the cross-roads (Sept. 11, p. 331), and has been for some time, because one leg is trying to go one way and the other leg another. There is an almost complete divorce between those entrusted with leadership and those who have to do the bulk of treatment and research. In general medicine or surgery, when a specialist gives up his hospital beds, by which he continually adds to his skill and knowledge, he loses influence. In psychiatry the opposite is true. He a doctor must give up active treatment as soon as possible in the hope of attaining the only positions of responsibility—security, and influence—as a medical superintendent behind an office desk or as an eminent consultant generally without hospital beds of any sort. Psychiatry is organized to-day on the Royal Colleges would be if an essential step to a seat on the Council, or even a Fellowship, were to give up active clinical practice for consultative work and the administrative control of other doctors. This state of affairs is more appropriate to religion than to science. The position will not

ch improved by simply making the D.P.M. a little harder, insisting that our future consultants should spend at least 3 years learning to treat patients in mental hospitals before ending to detached psychiatric bishoprics. A more radical change is necessary.

The provision of psychiatric beds in general hospitals is vital to future progress. At the least it will provide an entree to the psychiatrist to remain a clinician with modern experience in treatment, and with opinions and influence derived from this experience. In any future planning these beds must remain as independent units and be kept strictly in the sort of hierarchy at present approved of by the Board of Control. Unfortunately, such an arrangement is not possible in mental hospitals; but the law still ordains that nobody but the medical superintendent can have any responsibility for a patient's treatment, and that clinicians can be no responsible except that derived directly from him, making these observations I do not wish to criticize any high psychiatric positions to-day. They are equally victims of the system, and I know personally how well they carry out their impossible tasks.

The unnatural organization of psychiatry is not only bad in practice but in principle. With an authoritarian and heresy-hunting is inevitable. Clinical progress is continually hamstrung. In some institutions psychotherapy is pressed; in others, insulin or convulsion therapy or prefrontal leucotomy. Through no fault of their clinicians some hospitals took ten years to introduce the malarial treatment of general paralysis. At present hundreds of schizophrenics drift into chronicity. Their health might have been maintained had not co-ordination between administrators and clinicians in treatment broken down. Even with the wartime shortage of staff a planned attack on the recoverable stages of this disease might have been made in regionally distributed treatment centres had therapists had any share in organization, had administrators better personal acquaintance with the problems of treatment. Scientific psychiatry emerges in a sorry tattered state from every new battle for advance, whose issues are decided less frequently by impartial judgment than by politics and authority. Our internecine wars make us the ring-stock of our medical colleagues, and are reminiscent of the age when theologians discussed how many angels could dance on the point of a pin, and the Pope's dictum was sufficient to decide whether or not the earth moved round the sun. I wish this might go if psychiatry could put first things first in the general medicine of to-day. The competent doctor should be given control of his beds and out-patient clinic, and influence in psychiatry become dependent on the skill he shows in treatment, teaching, and research.—I am, etc.,

WILLIAM SARGANT.

WILLIAM SARGANT.

Symptomless "Phthisis" and Artificial Pneumothorax

SIR.—Dr. A. Niven Robertson's letter (Sept. 18, p. 373) may be read and digested, save the public from countless errors and the profession from much discredit. He reminds me that artificial pneumothorax is "merely a local splint" which, if any, influence on the underlying general disease. The dictum that every patch of "phthisis" which can be sealed only by radiography should be treated by artificial pneumothorax is about as scientific as would be the dictum that every fracture, whatever its condition or duration, should be treated by a splint. A simple fracture of, say, the forearm be (a) quite recent and capable of going wrong, (b) partly healed and either progressing favourably or going wrong in any way, or (c) quite healed in good or bad position. Moreover, even a simple fracture may be due to some general disease the progress may be seriously affected thereby. A splint may be "indicated" in (a), may be either helpful or harmful in (b), but would be worse than useless in (c), and in no case would it attack the *causa causans*. A patch revealed by radiography in the absence of symptoms may be evidence of (in reverse order): (c) an infection which has subsided, (b) an infection which is subsiding naturally, or (a) a recent infection which, though active, has not yet evoked the usual constitutional symptoms. Careful watching and hygiene are necessary in any case, but until there is good reason to believe that the case belongs to class (a) a splint, in the form of A.P., may do

much more harm than good, and is definitely contraindicated. The analogy is no more perfect than most analogies, but I hope all who have missed Dr. Robertson's letter will look it up and study it.—I am, etc.,

Ambleside.

J. PRICE WILLIAMS.

Mass Radiography and After

SIR.—I was glad to see the note by Dr. A. Niven Robertson (Sept. 18, p. 373) warning against the indiscriminate employment of surgical measures in children with tuberculous chest lesions. There is an enormous disproportion between the numbers of those infected with tubercle and of those who suffer from it. In the course of 30 years' special tuberculosis practice I met with many cases of presumably tuberculous chest lesions which were quiescent and had given no trouble for years; and in some of these there was clear evidence of exposure to tuberculous infection in childhood.

When minimal tuberculous chest lesions are discovered by radiography we should first make sure that they are progressive or likely to be so and then investigate the conditions of life. The breakdown in health seldom happens without contributory factors, and surgical measures, though valuable, will not replace hygienic precautions and education.—I am, etc.,

Farnham

F. R. WALTERS, M.D.

Management of Pleural Empyema

SIR.—In your issue of Sept. 25 (p. 383) Mr. P. R. Allison has described the treatment of empyema. Without wishing to be controversial, may I question his recommendation of repeated aspiration for non-localized empyema and advocate air-tight suction drainage instead? To perform open drainage of the chest cavity in the presence of a pleural effusion which has not yet become circumscribed by adhesions would be a well-recognized surgical fault, but will Mr. Allison tell us what possible advantage repeated aspiration may have over continuous air-tight drainage by suction? The latter can be effected painlessly without moving the patient from his bed, and is often followed by rapid recovery without troublesome sequelae. An objection expressed by Mr. Allison against air-tight suction drainage is that "any system of closed drainage tends to focus attention on the apparatus rather than the empyema cavity." I would like to know on what observations this arresting remark is founded, and in what way air-tight suction drainage has been proved disappointing in his own hands.—I am, etc.,

Kew Gardens, Surrey.

HAROLD BLURROWS.

Treatment of Lupus Vulgaris

SIR.—In the *Journal* of Sept. 18 in an article on the treatment of lupus vulgaris it is stated that since the introduction of the Finsen and Finsen-Reyn lamps nearly 40 years ago nothing has been discovered to take their place. This is not the case. In July, 1928, at the annual meeting of the British Association of Dermatology and Syphilology Dr. Lomholt of the Finsen Institute described his modification of the Finsen lamp. This is much superior to the earlier models, and, indeed, in 1933 had entirely superseded the Finsen lamp even in the Finsen Institute at Copenhagen. The time of treatment is reduced by half, and each patient does not need the services of a nurse, as is the case with the earlier lamps. There are three Finsen-Lomholt lamps in the Skin Department of the Royal Infirmary, Edinburgh, the only voluntary hospital in the British Isles to be so equipped. One nurse is able to look after the three patients under treatment at the same time.

The Finsen-Lomholt lamp was briefly described in a lecture which I delivered to the Border Counties Branch of the B.M.A. in Nov., 1936, the lecture being published in the *Journal* of Jan. 23, 1937. That public health authorities are awakening to their responsibilities in the treatment and care of lupus patients is shown by the fact that in 1938 the Glasgow Public Health Department installed three Finsen-Lomholt lamps in their tuberculosis dispensary.

The idea of special centres for the treatment of lupus vulgaris is not new. As far back as the early 1920's the late Sir Norman Walker outlined a scheme for treatment centres to be situated in Edinburgh, Glasgow, Aberdeen, and Dundee. I do not know if his views were published. But I know that at that

time he was in frequent consultation with the Scottish Board of Health on the subject. In fact he frequently had members of the Board visiting the lupus clinic between 1919 and 1923, and he induced the Board to authorize public authorities to pay the fares of lupus patients coming to the clinic for treatment.

The idea of a special colony for lupus patients is not new either. In 1922 in a paper prepared for the annual meeting of the British Association of Dermatology I outlined a scheme for a lupus colony, not only for advanced cases but for cases of all ages and at all stages. Through lack of time the paper was not read, but in the scheme I outlined the colony was to be made self-supporting so far as possible.

These patients have a miserable existence. They are frequently economic liabilities, but with proper treatment can be made economic assets. It is more than time that the public—and professional—conscience was awakened to the miseries of their lot.—I am, etc.,

Workshop.

ROBERT AITKEN.

Health and Tonsillectomy

SIR,—In your article "Health and Tonsillectomy" in the *Journal* of Sept. 11 it is pointed out that the incidence of nasopharyngeal disease, otitis media, etc., in the tonsillectomized group was about the same as in the non-operated-on group. Surely this statement proves that the operation has been, to say the least of it, successful, for those who were operated on were children who were much more subject to nasopharyngeal disease than the average child, and therefore, if they are now as good as the average child, the operation must have done good.

I have been medical officer to two or three boarding schools for 30 years, and it is always a relief to me to find that children have had tonsils and adenoids removed, for in my experience they rarely get mastoids or otitis media. When I began to practise in England in 1906 when tonsils and adenoids were rarely removed I always had on my books 2 or 3 children with discharging ears; for the last 20 years I have had practically none. I think this proves that on the whole this operation has been of great benefit to the community.

Another point in favour of the operation is that I do not see nearly so many cases of catarrhal deafness in the middle-aged.—I am, etc.,

Limpfield, Surrey.

G. D. LAING.

Wartime Diet for Peptic Ulcer Patients

SIR,—Having recently been laid low for four months as a victim of peptic ulcer I have been enabled to view the problem of treatment both as a patient and as a doctor. As a patient I found difficulty under wartime restrictions in obtaining a sufficient quantity of the right types of food to provide a full and varied diet, and I wrote to the Ministry of Food suggesting that various changes should be made, such as the temporary allocation of more "points" coupons. I received a reply to the effect that as the Minister's advisers on invalid dietary had ordained for ulcer patients a priority of three eggs per week and a quart of milk a day no further provision was considered necessary.

Not content with this answer I have reopened the matter with the Ministry and wish to obtain sufficient evidence that a strong body of medical opinion is in favour of temporary food concessions being made for ulcer patients under proper safeguards which the Ministry would devise. My object in writing this letter is to ask all doctors who have had a peptic ulcer themselves during the war to write to me, Dr. J. B. W. Rowe, Kodak Ltd., Harrow, Middx., giving their opinion as to what changes should be made. Opinions from other doctors who have found difficulty in treating peptic ulcer patients owing to inadequate dietary would also be welcomed. I shall then be in a position to present some statistical evidence to the Ministry.

Changes which suggest themselves to me as being desirable are: (1) a substitution of cheese for butcher's meat; (2) a temporary increase of "points" coupons to provide extra easily digestible foods such as cereals, porridge, syrup, etc.; (3) a priority on portable types of food—such as biscuits—so that a patient can always have a few with him and eat them when necessary, since meals at 2 to 3 hours' intervals are so important;

(4) a priority for the supply of fish of a suitable type (where there is any) so that the patient's wife does not have to spend long hours in queues and can go home and have her husband's meal ready at the right time.

There is another and very important aspect to this question about which I have already written to the Ministry of Labour so far with no satisfactory result. A rough estimate of the number of men who are suffering or have suffered (with gravity to recurrence) from peptic ulcer in the United Kingdom in round figures is 500,000, and I am told by colleagues that there has been a distinct and notable increase in the incidence of peptic ulcer lately. The morbidity is high and lost time amounts to anything from one to six months, and the fact that brain workers are more liable to the condition than manual workers means that key men are the most likely people to be affected, with a consequent greater possibility of industrial disorganization occurring. All this means that every possible step should be taken to cure and to keep people liable to peptic ulceration working, and one of the best ways to do this is to provide sufficient easily digestible food for meals at regular and short intervals.—I am, etc.,

J. B. WRATHALL ROWE.

Recovery of Bladder Function after 21 Years

SIR,—A patient aged 45 was operated on in 1922 by a surgeon who shortly afterwards died. A suprapubic cystotomy was performed, apparently for impassable prostatic stricture. He carried on his work for 21 years with a succession of suprapubic tubes, which he changed for himself. There was no severe cystitis. About April, 1943, great difficulties arose. There was great straining, the tube would not go in properly and he kept constantly wet. It was also difficult to get action of the bowels. He consulted Dr. Verner of Newport, who sent him to me.

The prostate was very large, and operation was advised. On Aug. 11 the largest prostate I have ever seen—decidedly larger than a coconut—which filled the bladder and blocked the pelvis, was removed. Bleeding was furious, and it was necessary to sew up the prostatic bed completely, and give a large blood transfusion. Three days later a Foley catheter was introduced per urethram without any difficulty, and the thin rubber bulb distended with water between the sutures so as to reproduce a prostatic cavity. There was a secondary haemorrhage a fortnight later, which was controlled without much difficulty. This delayed convalescence, but he passed water naturally at a month, and was practically healed and quite dry when he went home. There was neither straining nor frequency.

It is remarkable that the bladder should recover its function without any hesitation or bungling after so many years. I may be that the enormous size of the prostate is connected with the fact that there was no bladder pressure to control it.—I am, etc.,

Bristol.

A. RENDLE SHORT.

Vomiting Sickness in Jamaica

SIR,—In your issue of Sept. 25 (p. 392) there is a letter from Dr. A. A. Wright which would suggest that this malady is a new one. He makes no reference to, in fact appears to be ignorant of, the exhaustive research into this condition by H. H. Scott recorded in the *Ann. trop. med. and Parasit.* Liverpool, 1916, 10, 1, under the title, "On the 'Vomiting Sickness' of Jamaica."—I am, etc.,

London, W.1.

HUGH S. STANNUS.

Arsenicals in Vincent's Infection

SIR,—The recent article "Misuse of Intravenous N.A.B. for Vincent's Infection" calls for some comment. In the first place the title of the article is ill chosen. Surely it is better that it be headed "The Use of N.A.B., etc.," and further elaboration to show whether that use is justified or not. Such dogmatism is apt to mislead the less experienced and those who, for want of time, fail to analyse the article carefully.

I do not think it is justifiable to label intravenous arsenical as useless in the treatment of Vincent's infection on the slender and somewhat unreliable and incomplete evidence produced. The "two recent illustrations" quoted are open to serious criticism. In the first case, and in many of the others quoted

he lesions in the mouth developed in the course of treatment with intravenous arsenic for another disease, and after a number of such injections had been given. It is a well-established fact that Vincent's organisms exist in the mouths of healthy people, and only become pathogenic when the opportunity presents itself. Is there not a distinct possibility that they may become drug-resistant and display their pathogenicity in spite of the presence of arsenic? In the second case there was deep jaundice, and it is well known that under such conditions the resistance to infection is considerably lowered.

There must be ample evidence available to show that intravenous or intramuscular arsenicals are of use in the treatment of Vincent's infection. Personally, although I have no actual records by me, I have seen a large number of cases of confirmed Vincent's infection clear up as if by magic after one or two injections. With regard to the expense, it costs approximately 3s. to treat each case, and if Dr. Eric Jewesbury has ever experienced the pain and discomfort attendant upon a large number of local treatments I am sure he will agree that the very remote risk of complications after arsenical injections is well worth taking. It is to be hoped that Dr. Jewesbury will produce some much more convincing figures and cases to show that arsenicals are of no value in otherwise normal cases of proved Vincent's infection, and that, having produced his evidence, he will head the article "The Value of Intravenous Injections of N.A.B. in Cases of Vincent's Infection."—I am, etc.,

Basingstoke.

JOHN J. DAVIS,
Major, late R.A.M.C. (T.A.).

SIR.—A great many dental surgeons will welcome Squad. Ldr. Eric Jewesbury's article (Sept. 18, p. 360) explaining the need for "careful local treatment" and the misuse of intravenous N.A.B. in this disease. It is not exceptional for a dental surgeon, after having set the patient on the right line for complete recovery, to have the patient's confidence in his constructive plan of local treatment—in some cases necessarily laborious—upset by the G.P.'s inadvisably offering the get-you-better-quickly promise of intravenous arsenic.

In the "sore-gum" type of subacute Vincent's disease, and in the very destructive but painless chronic type, total eradication of the infection may entail a great deal of dental reconstruction (as I described in the *Journal*, 1936, 1, 1104) before every nidus from which recurrent attacks can originate has been eliminated. It is, of course, natural for the patient to grasp at any much simpler and less expensive treatment, but the result of the suggestion that intravenous medication will successfully combat the infection invariably leads the patient to think that there is no reason to fuss with the finicky business of oral hygiene. He therefore relinquishes his efforts to co-operate, and as a consequence his condition deteriorates. It is disillusioning for him subsequently to discover that the intravenous arsenical had done no good, and Dr. Jewesbury's caution that it may indeed do harm is a timely corrective.—I am, etc.,

London, W.1.

C. BOWDLER HENRY.

SIR.—I am impelled to write in relation to possible misconceptions which may arise from Squad. Ldr. Eric Jewesbury's article, which is entitled "Misuse of Intravenous N.A.B. for Vincent's Infection." This article refers apparently to infection of the mouth only. Unfortunately the term "Vincent's angina" is used throughout. This term is better restricted to infection of the throat, especially since there can be little doubt (following the work of Dobbs, etc.) that the two infections are aetiologicaly distinct. "Vincent's infection of the mouth" not being primarily caused by Vincent's organisms, it is not surprising that N.A.B., locally or intravenously, is usually ineffective. Vincent's angina of the throat is entirely different. N.A.B. applied locally is a startlingly specific for this disease. (It is unnecessary to risk the slight dangers of intravenous use.)

I am appalled at the amount of ignorance which prevails on this subject in some quarters. I have recently seen two cases of quite severe chronic and recurrent Vincent's infection of the tonsils which had been treated in various ways for months without much response. In each case symptoms were relieved after the first application of N.A.B. paint, and healing occurred rapidly. In the last two months I have also treated some nine cases of more acute Vincent's infection in the same way with the same rapid response.

I am not pretending to deduce anything new, but merely wish to point out that local N.A.B. is a well-recognized and spectacularly specific drug for Vincent's angina (of the throat), but it is frequently not being used.

Incidentally the N.A.B. may be used dissolved in glycerin (or Mandl's paint), about 0.5 g. to the ounce. The debris should first be removed from the ulcers with a swab-stick, and the paint carefully applied into the base and around the edges of the ulcers.—I am, etc.,

Old Hunstanton.

W. P. U. JACKSON, M.R.C.P.

Arsenical Encephalopathy

SIR.—With regard to the article by Nelson, McGibbon, and Hughes (May 29, p. 661), I read with much interest and some surprise the details of four of their cases of the above complication. I should like to point out that in these days there must be few venereologists who begin the treatment of latent, late congenital, or tertiary syphilis with an arsenical preparation in addition to bismuth. It seems now to be a well-established principle that, in cases of tertiary syphilis, one is wise to start treatment with potassium iodide by mouth, daily, for two or three weeks, followed by a course of bismuth intramuscularly once or twice weekly until ten injections have been given, then small amounts of an arsenical preparation—e.g., neosarsphenamine 0.15 g.—are given intravenously once weekly and the dose gradually increased. The same would apply to a case of late congenital syphilis with a gumma. In latent syphilis one could omit the potassium iodide and commence with a course of bismuth.

Neglect of these precautions is liable, at least in tertiary syphilis, to give rise to serious consequences in the nature of a Jarisch-Herxheimer reaction, which may be fatal if a vital organ is involved. The authors quote four such cases: the first one probably a late latent syphilis (history of penile ulcer in 1910), in which the Wassermann reaction was found to be positive, though clinically the case was one of lymphogranuloma venereum. The second case was one of late congenital syphilis with a gumma (a woman aged 22 years who was 27 weeks pregnant). The third case was a 24-year-old multigravida (32 weeks pregnant) with latent syphilis. The fourth case was one of primary syphilis (a woman 20 weeks pregnant) with a B.P. 150/90 and slight albuminuria following a fit. In each case the treatment was begun with N.A.B. and bismuth. The first three cases died in coma, evidence of haemorrhagic encephalopathy being found at necropsy. The fourth case became comatose shortly after treatment commenced, but eventually made a complete recovery. This last case may well have been an eclampsia or a hypertensive encephalopathy in a pregnancy toxæmia. There was no pathological evidence to support the diagnosis of haemorrhagic encephalopathy, though the latter cannot, of course, be excluded.—I am, etc.,

C. B. ARSCOW,
Capt., R.A.M.C.

Spinal Anaesthesia for Labour

SIR.—It is possible that junior obstetric surgeons reading the article by Dr. Harold Burton on low spinal anaesthesia in labour with cardiac failure may feel tempted to give this method a trial.

I would most earnestly ask that before they do they should read the literature on the subject or even consult the standard textbooks. I feel that even the most superficial acquaintance with the literature on the subject will cause them to reconsider their decision to employ any form of spinal anaesthesia during labour. Furthermore, I am convinced that the giving of a spinal anaesthetic to over 100 normal cases "in order to develop the technique fully" is a procedure which will find little favour with the majority of obstetricians.—I am, etc.,

WILLIAM J. CLANCY,
Obstetrician, City General Hospital, Sheffield.

Register of Medical Auxiliaries

SIR.—The Council of the Board of Registration of Medical Auxiliaries, of which we, the undersigned, constitute the medical members, would very much appreciate the privilege of being allowed through your columns to draw the attention of the medical profession to the objects for which the Board was formed in 1936, and to ask for the full co-operation of the profession in the use of the Register.

Medical auxiliary work is taking an increasingly important part in the treatment of disease, yet at present it is open to anyone, qualified or not, to practise this type of work. The purpose of the Board is to provide a *Register* of qualified persons who are guaranteed to have undergone an adequate course of training, passed a recognized examination, and have undertaken to maintain a good ethical professional standard. By consulting the *Register* doctors or members of the public may assure themselves of the training and status of the person whom they employ for medical auxiliary work. The Board itself is a body composed of duly appointed medical practitioners and representatives of each recognized branch of medical auxiliary work. It has provided a standard *Register* of the following groups: chartered masseurs/leuses; radiographers; biophysical assistants; dispensing opticians; chiropodists; orthoptists and speech therapists; and can confidently recommend to the medical profession and the public those persons who are on its *Register*. Support has been given us by many hospitals, public bodies, and individual practitioners, but there is need for the whole medical profession to make use of the *Register* if it is to serve to the full the purpose for which it was instituted. Though at present, owing to the war, it is impossible to publish the *Register* in full each year, it is possible to supply any practitioner with the information he may require as to the qualifications of persons on the *Register*. Inquiries should be addressed to the secretary of the Board of Registration of Medical Auxiliaries.—We are, etc.,

H 11 for Cancer

SIR,—In answer to Dr. G. W. Blomfield's letter (Sept. 25, p. 403) I should like to say that in my series of cases treated by H 11 all case records can be obtained at the hospitals where I have acted as pathologist. I am quite familiar with research procedure as I held a research grant from the B.M.A. for three years at the Middlesex Hospital. Furthermore, I held a research fellowship for one year in Liverpool. Of course a biopsy was taken from my case, and as an added precaution I reported my findings to the late director of the Medical Research Council.—I am, etc.,

Southport.

JOHN H. HANNAN.

Specialist Courses for Service M.O.s

SIR,—May I say a few words in support of Dr. L. W. Aldridge's excellent letter (July 17, p. 88).

My case must be typical of thousands of Army medical officers and so I make no apology for stating it. After qualifying I spent a year as a general house officer in a small hospital, where I got a "smattering" of all the branches of our art. This served to convince me that my future career lay in the realm of surgery, and I was just beginning to feel my feet when I was called up. Since then for the past 18 months I estimate that I have used a scalpel not more than a dozen times, and then for such minor operations as excision of toe-nails and sebaceous cysts. I well remember after a year in the Army how thrilled I was when some kindly civilian surgeon allowed me to perform a circumcision. I quite realize that in war such a state of affairs is inevitable; young physically fit medical men are not plentiful, and so we must be employed with the fighting Forces in the front line, where there is little opportunity of doing surgery or, for that matter, reading it. Refresher periods at C.C.S. or military hospitals might help a little, but the administrative difficulties of such a policy are very great.

What of the future after the war for us young would-be surgeons? Many of us have married during the war: are we to return to a hospital post at £150 per annum (no hospital will pay us any more with our lack of practical experience for two or three years)? Are we expected to keep a wife on such a salary, or must we take up general practice, for which we have no aptitude and little inclination? Some old stagers say that it is our own fault for getting married; would

they have all Army officers bachelors until after the war? As a last resort a lot of us will refuse to be pushed into general practice by economic necessity; our wives will make the sacrifice, they will forgo a home and children for a few years and continue, if possible, to work; I think that the nation and the profession owe to the men who are fortunate enough to return from active service a better deal than that.

Therefore in these days of talk of rehabilitation let there be some plan for the rehabilitation of the Army M.O. Can something be arranged whereby we can reacquire the knowledge we have lost during the war, so that we can command a reasonable salary in the work of our choice and continue with our clinical aspirations? Let us not be driven into general practice merely to keep body and soul alive. Surely such a state of affairs would produce not only unhappy but bad general practitioners—a most important point at this time, when all our efforts are being directed towards giving the general public a better medical service.—I am, etc.,

E. M. LEYLAND,
Capt., R.A.M.C.

B.N.A.F.

Medical Services for the Merchant Navy

SIR,—As one who has had some short experience of the conditions existing during the present rapid turn round of shipping, may I state my views on this subject. The following points against the present system become immediately apparent

1. The other Services—i.e., the Navy, Army, and R.A.F.—have a full-time medical service, but except on board passenger vessels the Merchant Navy has not.
2. The other Services have a hospital service; the Merchant Navy has not, and with few exceptions is dependent upon local authority and voluntary hospitals.
3. In the United States there are huge, well-equipped hospitals purely for seamen. The funds for these come from a levy made by the Seamen's Union. (This is a very wealthy union.)
4. In the special conditions prevailing in wartime, ships' companies have to be made up at the last moment, and for this and many other reasons unfit men undoubtedly do have to sail, and even those infected with gonorrhoea have been given a box of sulphapyridine tablets with instructions to the master or chief steward, no doctor being carried in the ship.
5. No one can expect the "Federation doctor" to be able to give a real examination. These doctors are nearly always busy general practitioners, and with the best will in the world they just cannot do it. The notice given them is usually short. I think that in some ports there is no such examination.
6. As a rule there is no record available to a doctor examining a merchant seaman.

I therefore suggest that these objections could be met by some such scheme as the following: A complete separate Merchant Navy Health Service should be established to deal with all questions of seamen's health, including initial fitness for the job on first going to sea; a medical examination before each voyage; a non-infectious illness and accident service in each port or anchorage (a service of this nature has been set up in the Clyde Anchorages Emergency Port); amphibian ambulance service in each port or anchorage; appropriate hospital facilities strategically situated (these could be either *ad hoc* hospitals or, more economically, beds and/or wards set aside in local or E.M.S. hospitals by arrangement with the hospital officer); proper facilities for the treatment of V.D. at all ports. There is also a sound case to be made out for a liaison officer from this force to advise the Board of Trade on the improvement of conditions on board ship.

This medical service would not only examine but also treat seamen. In small ports certain of these duties could be combined with the port medical officer's duties and/or carried out by part-time practitioners. A section should be devoted to research into nutrition, vocational training, and initial suitability for the work. It appears to me that if some such service as this were available (and it is surely not so much more than the other Services already have) then little objection could be raised by seamen to a medical record card, attached to the seaman's own card, which he must already carry. Such a scheme as the above could be financed either purely by the State or by the State along with the Shipping Federation, who so far appear to have shirked their responsibility in this matter.

The favourite bogey of "free choice of doctors" can hardly be produced against a State scheme for merchant seamen, as they have never had this except when on shore for some time.

One of the essential prerequisites of any State medical scheme already exists here, in that all seamen are now "on the pool," and are paid whether at sea or awaiting a vessel.

There is a great deal to be said for introducing some such scheme as this, at the present time.—I am, etc.,

Mansfield.

W. P. FORREST.

"The Classics"

SIR.—The question whether a knowledge of the classics is helpful to one taking medicine as a career is interesting. Experienced teachers claim that this knowledge leads to clarity of thought and expression, a power of understanding the views of others, and a broader outlook. Undeniably a boy knowing some Latin and Greek will understand, and remember, and spell scientific terms the better for it.

Does not the modern drift from the classics arise more from the way they are taught? as Prof. Major Greenwood suggests. If a boy is making these subjects his life work the system may be defended and the considerable time spent in learning to write in these languages justified. When I was a boy I spent much time in writing what were politely termed "Latin verses" and translating portions of the *Times* into Attic Greek. So that my style should be good, the authors chosen for my reading were selected for the purity of their language rather than the interest they contained.

Supposing a new outlook were taken and boys taught to read rather than write, and the authors chosen for their human interest and modern outlook, I am sure the boy would learn with much more pleasure. Most of us have been "bored stiff" in trying to understand how Caesar built his famous bridge, or Priam harnessed his complicated chariot, whereas we should have enjoyed Pliny giving an eye-witness account of the destruction of Pompeii, or the adventures of Lucian as an "airman." Later in life, when we realized that the medical practitioners in ancient Rome were either slaves or ex-slaves and traced the similarity between the Beveridge report and the idea of "panem et circenses," we should be forced to realize that the Romans (and Greeks) thought much as we do and faced similar kinds of problems.

At 63 I still think a man with even a humble knowledge of the classics "has a little something the others have not got" (to quote a pre-war trade slogan), and is the happier for this.—I am, etc.,

Badon, Bristol.

W. BALY PEACOCK.

Obituary

G. H. EDINGTON, M.D., D.Sc., F.R.C.S.

We regret to announce that Col. G. H. Edington died on Sept. 24 in the Western Infirmary, Glasgow, where he had been visiting surgeon for many years. He held many important posts, gave valuable service over-seas during the last war, and was a member of the General Medical Council for 12 years.

George Henry Edington, eldest son of G. B. Edington, iron-founder, of Glasgow, was born on Jan. 10, 1870, and after schooldays at Kelvin-side Academy studied medicine at the University of Glasgow and at King's College, London. He graduated M.B., C.M.Glas. with commendation in 1891, took the English Conjoint Diplomas in 1896 after proceeding to the M.D. (also with commendation), and became F.R.F.P.S. in 1897; he received the D.Sc. of Glasgow in 1913 and was elected F.R.C.S.Eng. in 1931 without examination. After holding a number of minor clinical and academic posts in Glasgow he was appointed in 1908 to the chair of surgery at the Anderson College Medical School. Five years later he followed the late Sir George T. Beatson as visiting surgeon to the Western Infirmary, and soon afterwards was appointed lecturer in clinical surgery at the University; he was also extra honorary surgeon to the Royal Hospital for Sick Children, and consultant to a number of other institutions. From 1922 to 1927 he was honorary physician in Scotland to King George V. He was a Past-President of the Royal Faculty of Physicians and Surgeons of Glasgow, and represented that body from 1928 to 1940 on the G.M.C. He served for some years as editor of the *Glasgow Medical Journal*.

Col. Edington had a lifelong interest in the Volunteer and Territorial Force movement. He embarked for duty over-seas during the last war as commanding officer of the Lowland Field Ambulance with the 52nd Division, and saw service at Gallipoli and in Egypt; later he was in command of the 78th General Hospital at Alexandria, A.D.M.S. of the Lowland Division, and for a time senior medical officer at a base camp in Palestine. In civil life he took an active interest in the work of the Red Cross Society and became chairman of the Scottish Executive Committee in 1930; the Red Cross movement in Scotland owed much to his enthusiasm. He became a member of the Glasgow University Court in 1939, and in the following year was elected president of the Royal Philosophical Society of Glasgow. He joined the B.M.A. in 1893 and held office as vice-president of the Section of Surgery at the Annual Meeting in Dublin in 1933; he was also a Fellow of the Association of Surgeons of Great Britain and Ireland. During the present war he served on the Scottish Civil Nursing Reserve Advisory Committee and on the Council of the Scottish National Blood Transfusion Association. Some years ago he was appointed a deputy-lieutenant and J.P. for the County and City of Glasgow.

A fellow-member of the Moynihan Club writes:

George Edington had the gifts of geniality and a keen sense of humour, so that he was always a delightful host and a charming travelling companion. I well remember visits with him to surgical clinics in Bordeaux, Prague, Basle, and Zurich. He was full of quaint observations and humorous remarks of what he saw, and in this way always added to the enjoyment of our visits abroad. One would constantly catch a merry twinkle peering through his glasses and a whimsical expression as he chipped one of the party or burst forth in exclamation at some unusual occurrence. In one clinic the French surgeon in charge was performing a long list of operations, chiefly abdominal, and laparotomy disclosed in one case a uterus containing large fibroids. The operator proceeded to remove it, and to our astonishment used a Lawson Tait myoma screw, an instrument which few of us had ever seen at all and still fewer had seen in use. As he twisted the corkscrew-like end into one of the fibroids we heard Edington's whispered remark, "He puts it in like a Scotsman!" Dear George Edington, as he was to his older friends; equally beloved by his younger ones, charming to all. He will be sadly missed from among us. Of his operative work I can say nothing as he was not doing much operating by the time I met him, and his contributions to surgery are too well known to comment upon, but with thoughts of the kind way in which he entertained many of us at his club when we were in Glasgow, of his witty reminiscences of his experiences in the out-patient department of his hospital, and his invariable kindness and helpfulness, I would pay a brief tribute to him in these few recollections.

ADAM FULTON, M.B., B.Ch.

The news of the death on Sept. 28 of Adam Fulton, at the age of 74, brings back pleasant memories of a man once prominent and greatly liked in B.M.A. circles. After a successful student career in Belfast he qualified as M.B., B.Ch., B.A.O., and settled near Nottingham, where he built up a large colliery and industrial practice. He joined the Association in 1904, and in 1910 came to the Annual Meeting in London as Representative of Nottingham. He continued as a Representative until 1914, was a member of the Council from 1913 to 1920, and a very active member of many committees. In 1920 he accepted an invitation to become a Divisional Medical Officer of the Ministry of Health, and was thus lost to active Association work though always keeping up his membership and his interest in its work.

Fulton was a general practitioner of a very fine type, who secured for himself the confidence and affection not only of his patients but of his colleagues, and both made heavy demands on his energies which were cheerfully accepted. He was very prominent in the struggle over the National Health Insurance Bill, and took a characteristically sane part in the discussions. He was a man of strong moral courage and never concealed his opinion—not too popular at the time—that if the main demands of the profession were met, as they eventually were, the new health service would be a boon to the public and to the profession. He was vice-chairman for some years of the Notts Insurance Committee, and in other ways, both locally and centrally, made his influence so felt that it was no surprise when he was invited to go to the Ministry. I know that his

advice was greatly valued by Smith Whitaker, then the chief medical adviser to the Ministry on the Insurance side, and by Sir Robert Morant, its secretary. Fulton's official duties, which were mainly concerned with Yorkshire, were carried out with his usual tact and sound judgment until the time of his retirement. But to me the quality of the man was best shown during the last war when on his Local Medical War Committee and in co-operation with headquarters he organized the doctors in his district in a way which was not surpassed in any other area. The Notts area was exceptionally heavily depleted of doctors, but Fulton and his colleagues met the situation with great ingenuity and courage, and originated many ideas for the more economical use of doctors, which the Central Medical War Committee was preparing to adapt for use throughout the country if the incessant drain of practitioners into the Army had gone on. The Armistice fortunately intervened.

Since his retirement he had lived in Harrogate, where he continued in a quiet way to make himself useful to his profession and his neighbours. The older members of the profession who knew Fulton would, I am sure, agree with me that it was a privilege to know and work with a man who had such a great fund of common sense and good humour. He was always listened to with great respect in any committee in which he took part. Fulton had no family, but no notice of his career which is more than formal would be complete if it did not mention that he often said that but for his wife's interest in his medico-political work he could never have thrown himself whole-heartedly into work for his professional brethren.

A. C.

A. I. SIMEY, M.D.

The following appreciation of Dr. Simey, supplementing the memoir published on Sept. 11, has been sent by Dr. J. N. Wheeler of Rugby.

A. I. Simey was an instance of all too rare combinations—a first-class classic devoting himself to science and medicine, and again a man with the qualifications and attributes of a first-class consulting physician, imbued with the unselfish motive of love of his old school, of which he had been senior classic and head boy in his time, and drawn by an unalloyed interest in youth, devoting his life to the health of that school as its medical officer. A classical education at a public school and university is a fine preparation for our profession, and there are very many of us who feel that it is a retrograde system which rushes a boy into the precocious specialization of First M.B. work while still in the upper forms of school. The former gives a man the basis of a mature mind's wider outlook in the choice of a profession, and we should remember that it was only the expected shortage of doctors to fill the demands of Government services which has introduced the element of far too early specialization.

Simey was full of selfless philanthropy in the best sense of the word. Never swayed by selfish ambition, he saw no higher aim than to devote his gifts to the service of the young and of his Alma Mater. He was full of acts of sympathy and kindness to little children, and of friendliness and hospitality to Rugbians past and present, and in the latter his wife took the share of a true and very gracious hostess. When he came to Rugby and was appointed hon. physician to the Hospital of St. Cross, this voluntary hospital was not yet more than a large cottage hospital of 40 to 60 beds. He left it a thriving and growing general hospital of the smaller class with more than double that accommodation. In this metamorphosis he played a large and untrump part as a member of the Board of Management and of its House and Finance Committee, always taking a very friendly interest in the nursing staff and their health and social activities. He was instrumental with Bernard Relfon and others in bringing to birth the Rugby and District Medical Society—a happy social and scientific medical association entirely free from political taint. His wide sympathies made him a most patient and wise counsellor and friend to his colleagues in difficulties arising in practice or in hospital work, and his retirement, forcing him as it did to leave the town and start work as a consultant in the South-Western Counties where he already had connexions, meant a really great loss to the rest of the profession in and around Rugby. As a physician he was a most exact clinical observer and accurate diagnostician, as well as an artist in note-taking. Records meant very much to him in the interests of the after-care of his patients, and when he retired he passed on their dossiers most helpfully to their subsequent medical advisers. He would also feed out whole case sheets to his R.M.O.s by bedside dictation at the hospital. His cultured scholar's mind was helped by a wide range of reading and an exceptional memory for the old classics, which were to him a never-failing source of colour and humour that ran through his thought and talk, his letters to his friends, and even these clinical notes.

He was an expert botanist and a born naturalist; the birds and the wild flowers were his friends and his hobby. He knew the haunts of rare wild flowers and ferns in many scattered parts of England. As a friend he was as strong as the Northern fells among which he grew and whose height and breadth he loved.

WILLIAM PASTEUR, M.D.

Mr. Victor Bonney writes: In the obituary tributes to the late Dr. William Pasteur his chief claim on posterity—namely, that he discovered, described, and put on the map of medicine for all time the condition known as massive collapse of the lung—is not made clear. I am sure that all those who served with or under him would wish that this, his outstanding achievement should be permanently associated with his name.

Dr. G. P. Smerwood writes: In the passing of Dr. William Pasteur the profession has lost one of the fast-dwindling members of the top hat and frock coat era who were the pioneers of the profession as it is to-day. Those of us who had the advantage of learning under his tuition must have a sad sense that with him has passed a real friend. To say he had dignity sounds too cold. There was a warmth and kindness blended with that dignity, a sort of paternal interest that he always seemed to take in his students, that must have left with all of them a life-long affection for "Bill" Pasteur. To this careful teaching and kindly interest many must owe a deep sense of gratitude. There was that in his whole manner, quiet, dignified, and kindly, that only one word, used in its true and unhackneyed sense, can adequately describe, and those students must feel that here has passed a true gentleman and a true friend.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The list printed last week of those upon whom titles of the degree of M.B., B.Chir. were conferred during July and August was incomplete. The names should read J. Hardy, V. U. Lutwyche, M. Sidgwick, and Mrs A. B. Willcock.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Arnott and Erasmus Wilson demonstrations and Museum lecture-demonstrations will be given at the College (Lincoln's Inn Fields, W.C.), Monday to Friday, Oct. 18 to Nov. 5. All the demonstrations begin at 4 p.m. and are open to advanced students and medical practitioners.

The Services

Temp. Surg. Lieut. P. R. C. Evans, R.N.V.R., has been awarded the George Medal for gallantry in services to the wounded after his ship had been damaged by an explosion. Enduring great pain, and with both his ankles broken, Surg. Lieut. Evans continued to tend the wounded for many hours.

Temp. Surg. Lieut. R. H. Jones, R.N.V.R., has been awarded the D.S.C. for courage and resolution in enemy coastal waters.

Surg. Cmdr. J. V. Williams, R.N., has been appointed a Commander of the Order of Orange Nassau for services to the Royal Netherlands Navy.

Capt. W. K. MacDonald, R.C.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Sicily. Surg. Cmdr. W. T. R. Chapman and Surg. Lieut.-Cmdr. S. B. Levy, R.N.V.R., have been awarded the R.N.V.R. Officers' Decoration.

The Order of Polonia Restituta (Officer) has been conferred on Acting Wing Cmdr. H. P. R. Smith, R.A.F., by the President of the Republic of Poland in recognition of valuable services rendered in connexion with the war.

Group Capt. W. J. G. Walker, R.A.F., Wing Cmdr. R. M. Outin, R.A.F.O., and Squad. Ldrs. M. O. Richardson, R.A.F., P. A. Gimson, and J. P. Houlihan, R.A.F.V.R., have been mentioned in dispatches.

CASUALTIES IN THE MEDICAL SERVICES

Fl. Lieut. GORDON WORSLEY BELLIS, who lost his life on Sept. 11 in a flying accident, was born in March, 1914, studied medicine at Charing Cross Hospital, and qualified M.B. B.S. in 1939. After a house post at Ashridge he was appointed to a commission in the R.A.F. on July 25, 1941. At the time of his death he was flying with a squadron operating over-seas.

Previously reported missing, believed prisoner, now recorded killed action, June, 1942.—Major H. M. R. Knight, R.A.M.C.

Prisoners of War.—Fl. Lieuts. D. A. Duthie, R.A.F., F. A. Forbes, B. I. Willey, F. R. Philips, A. F. Rutherford, R. R. McSwiney, C. Liddell, B. A. Stoll, H. J. Knox, R. G. Blackledge, J. Simpson, J. Connolly, B. L. N. Morgan, J. Lillie, F. W. Parke, M. H. Inmonth, R.A.F.V.R.

Correction.—Capts. (Temp. Majors) A. R. Clarke and W. C. Medhill and Capt. C. J. Cobbe, R.A.M.C., have been appointed J.B.E. (Military Division) in recognition of gallant and distinguished services in North Africa, and not O.B.E. as stated on Oct. 2, p. 439.

Medical Notes in Parliament

Discussion before the White Paper

Sir E. GRAHAM-LITTLE on Sept. 21 asked the Minister of Health whether he would explain in the forthcoming White Paper that the scope of the discussions he had been conducting with the Representative Committee was limited throughout by the stipulation that negotiations must be based on the acceptance of the decision taken by the Cabinet that a unified health service covering 100% of the population would be instituted, and that its local administration would be in the hands of local authorities under the ultimate control of a Minister who would be responsible to Parliament. Mr. ERNEST BROWN said that while he could not accept all the implications of the question, he agreed that the proposed White Paper reviewing this subject should make clear what preliminary steps (including discussions with the medical profession and others), had already been taken, and in what circumstances.

On Sept. 23 Mr. E. BROWN told Mr. Robert Morgan that a number of other organizations had communicated with him on the subject of a National Health Service besides representatives of the medical profession, local authorities, and voluntary hospitals. He had made it clear, however, that when the White Paper was published he would be ready to receive from organizations and persons interested any representations which they wished to make in the light of their study of it. It would therefore be misleading to publish at the present time a list of those organizations who had communicated with him in advance, other than those whom he especially invited to enter into preliminary discussions.

Nutrition in Newfoundland

On Sept. 21 Mr. ATLEE told Mr. Parker that he had recently approved proposals by the Commission of Government for launching a special nutrition campaign under the auspices of the Nutrition Council in Newfoundland. An expert dietitian was being engaged for the purpose, and certain other measures recommended by the council—e.g., for the importation of chemically reinforced flour—were also being introduced. It was hoped by these means to bring about a general improvement in dietary habits and to check at the outset the spreading of deficiency diseases, which, notwithstanding improved economic conditions, had lately tended to reappear.

Inoculation against Typhus

On Sept. 21 Sir JAMES GRIGG, replying to Mr. Leach, said that all inoculations in the Army were voluntary. Every soldier now going to North Africa was, however, encouraged to receive this form of protection against typhus, and the majority of the troops in this theatre of operations had been inoculated. This type of inoculation had only been used for a short time, and statistics were not yet available; but experience indicated that it was valuable both in preventing the disease and in lessening its seriousness if it was contracted. Mr. LEACH asked to what experience Sir James Grigg was referring when he said it was justified. Sir JAMES GRIGG: Experience in the pathological laboratories and in the few cases where typhus had appeared.

Medical Care of Civil Defence Casualties

Mr. ERNEST BROWN informed Sir Ernest Graham-Little on Sept. 21 that casualties occurring in Civil Defence units were treated in the same way as casualties in the rest of the civilian population, at first-aid posts and hospitals included in the Emergency Medical Services, which were staffed by experienced surgeons equipped with the latest methods for the treatment of wounds bacterially infected or contaminated by mustard gas or similar gases. In making these arrangements his officers had consulted the Ministry's consultant advisers, the Medical Research Council, and the experts attached to the Ministry of Supply, and the numerous instructions issued to medical staffs

of first-aid posts and hospitals were based on their advice. The Bunyan-Stannard envelope method of treatment was available for the use of those medical officers who wished to employ it.

Registration of Older Women

Opening a debate on Sept. 23 on man-power, Mr. ERNEST BEVIN said he had registered every man between 18 and 51 and all women between 18 and 47—10,000,000 men and 10,000,000 women. Of 33,000,000 people between 14 and 64, 22,750,000 were in the Services, Civil Defence, or paid employment. In the country there were nearly 16,000,000 males between 14 and 64, over 15,000,000 of whom were in the service of the country or in paid employment. Of 17,000,000 women between the same ages, 7,750,000 were similarly engaged. Over 1,000,000 other women were doing voluntary work, including nursing. Of single women between 18 and 40, 91% were working. That left only 9% for sickness and various ailments. More than 1,000,000 men and women over 65 were in paid employment. He was unimpressed by the medical arguments against registration of women between the ages of 45 and 50. When he had registered nurses and midwives up to 60 no one made a protest. He recognized that he would have to exercise great care with these women. None of them would be required to live away from home. There would be sympathetic treatment as regards their health and recognition of the difficulties of women in this age group. Sir HENRY MORRIS-JONES said that in women of these age categories inevitable disturbances occurred. The Government should not add anything to their difficulties which could not be proved to be necessary.

When the debate was resumed on Sept. 24, Mr. McCORQUODALE said that pleas for women between 47 and 50 in respect of physical fitness would be treated sympathetically. Mr. HOLDSWORTH asked if the appeal board would be able to go against a doctor's certificate. Mr. McCORQUODALE replied that if the doctor's certificate was not clear or if other circumstances presented doubt it might be arranged for the woman to have independent examination, but that was not to be the normal practice. In the main in these age groups a medical certificate would be accepted without hesitation. All the women in these groups would be regarded as immobile; those up to 46 were regarded as mobile.

Dr. RUSSELL THOMAS outlined the symptoms of the physiological and anatomical changes occurring in a woman between 45 and 51. The health fluctuated from week to week, and the question was not one of getting a medical certificate for two or three weeks. Proneness to accident and tendency to suicide were greater at that time of life than at any other. If a woman of that age said she was not up to work she should have the benefit of the doubt.

Shortage of Staff in Hospitals

Mr. MESSER said that, notwithstanding applications to bring hospitals under the Essential Work Order, nothing had been done, and a grave situation was approaching. The Ministry of Health had brought out a scheme to attract people to have treatment for tuberculosis, but wards were closed because there was no staff. At Harefield Sanatorium the domestic staff were in the ratio of two for every 58 patients—70 below establishment. Hillingdon General Hospital was 40 under establishment in the domestic department. He hoped the Minister would not wait for the Hetherington Committee's report before acting. The Middlesex Hospital had required a typist familiar with medical terms. The Minister had confirmed a refusal by the National Service officer to allow such a typist from Essex Insurance Committee to take the job. Yet the local employment exchange provided another typist who knew nothing of medical terms. Special hospital man-power boards might overcome such difficulties. At Clare Hall Sanatorium the pharmacist received his calling-up papers. Arrangements were made for another to take the job, but the Central War Pharmacy Committee said that if the man did so his reservation would be cancelled.

Replying to the debate, Mr. BEVIN said that he hoped to receive the Hetherington report in a few days. When he got it he would try to get the domestic side of the hospital service put right out of the registrations he had made and was now making. He knew that present difficulties reduced the efficiency of the trained nurses.

Notification of Venereal Disease.—Mr. ERNEST BROWN, on Sept. 23, told Lord Fermoy that he was not satisfied that the result of making venereal diseases notifiable would be to help in the control of the disease. He was keeping the matter under consideration, but there had not yet been time to judge the effectiveness of the measures already taken.

T.T. and Accredited Milk.—The proportions of the total sales of milk in England and Wales which are of tuberculin-tested and accredited standards are 6% and 35% respectively.

No. 37

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 18.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales a further rise occurred in the incidence of scarlet fever, 207, and diphtheria, 23. The notifications of these diseases have increased by 74% and 47%, respectively since the middle of August. Dysentery and acute pneumonia rose by 67 and 57 cases, and there were 220 and 25 fewer notifications of whooping-cough and measles respectively.

Half the increase in scarlet fever was recorded in two counties—Middlesex 61 and Lancashire 43. The increases in the incidence of diphtheria and acute pneumonia resulted from a general rise. Whooping-cough was slightly more prevalent in the southern counties; elsewhere notifications were down, largest decreases being in Warwickshire 61, and in Lancashire 48; the only large increase was in Leicestershire, with 44 more cases than in the previous week. The trend of measles is almost identical with that of the preceding week, the only variation of note being a decrease in Lincolnshire of 44 cases.

There were 67 more cases of dysentery—a large increase for the third consecutive week the cases have exceeded 200. The biggest of the new outbreaks were in Cumberland, Wigton R.D. 48, and in Devonshire, Exeter C.B. 16. A higher incidence was recorded from several areas, the largest returns in the week being in Kent 38, Rochester M.B. 26; in Middlesex 26, Rushmore Northwood U.D. 23; in Warwickshire 17, Birmingham C.B. 14; and thirteen boroughs contributed the 33 cases recorded in London. A total of 22 cases occurred in Hertfordshire, Buckinghamshire, and Bedfordshire, compared with 73 in the preceding week.

In Scotland the incidence of measles was down by 51, whooping-cough by 34, and diphtheria by 4 cases, but there were 36 more cases of scarlet fever. Dysentery fell by 24 cases and the largest returns were for Dunbarton County 21 and the cities of Glasgow 20 and Edinburgh 14.

In Eire an outbreak of whooping-cough in Co. Galway, Oughterand R.D. 33 cases, was responsible for the increase in this disease.

The Week Ending September 25

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,772, whooping-cough 1,480, diphtheria 757, measles 466, acute pneumonia 356, cerebrospinal fever 49, dysentery 270, paratyphoid 14, typhoid

Medical News

The Harveian Oration before the Royal College of Physicians in London will be delivered by Dr. W. E. Hume at the College on Monday, Oct. 18, at 2.30 p.m.

On the eve of St. Luke's Day, Sunday, Oct. 17, Sir Norman Birkett ("Onlooker"), who has recently paid a flying visit to Africa, will be appealing for medical missions in Africa as the Week's Good Cause at 8.40 p.m. Contributions should be sent to Sir Norman Birkett, at 2, Eaton Gate, S.W.1, marked "B.B.C. Appeal." The preceding religious service, to begin at 8 p.m., will be conducted by Dr. Clement Chesterman, M.R.C.P., who will speak on "Impressions and Experiences of a Medical Missionary in Congo." Dr. Chesterman is the hon. secretary of the British Advisory Board on Medical Missions, and a member of the Colonial Advisory Medical Committee.

A congress on tuberculosis, described as "international," was held at Budapest at the beginning of May under the presidency of Prof. Tomcsik. The chief subject for discussion was tuberculosis in wartime.

The *Klinische Wochenschrift* announces that a central bureau for "childless marriage" has been opened in Vienna. Its function is to assist in every way eugenically sound and childless couples to overcome sterility. If necessary, this assistance may include removal of costs. After the war an institute for investigating human sterility is to be developed from this bureau.

A donation of £5,000 has been given by Imperial Chemical Industries, Ltd., in response to the Oxford University appeal for £250,000 with which to found a department of ophthalmic research.

A new sound film called "Defeat Tuberculosis" has been made at the request of the Ministry of Health by the Ministry of Information. The film, which is intended for exhibition to the public, stresses the need for seeking treatment early, and shows modern methods of diagnosis and treatment of tuberculosis. It is now available for showing to "non-theatrical" audiences. It takes 10 minutes to run, but it cannot be shown on "silent".

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Antiochus Westcent*, London. SECRETARY, *Medaera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Postural Dizziness

Q.—My wife is 66 years of age. She has always been very active, and in fact does a large part of her housework now. When he is up and about she seems quite well, but she gets attacks of dizziness on getting up in the morning, and sometimes on turning over in bed. Once she is up the dizziness passes off in a few minutes. Specialists say that heart, eyes, and ears are all normal. (about 30 years ago she had a duodenal ulcer, and still strictly 'lets herself'). She has suffered from no other illness except that she has some fibrotic nodules in the back of the neck.

A.—Dizziness was defined by Soma Weiss (J. Amer. med. Ass., 1942, 118, 529) as "an abnormal sensation of unsteadiness characterized by a feeling of movement within the head without the experience of the external world or the patient himself being in motion." In this way dizziness differs from vertigo, in which the patient has the sensation that the outer world is revolving about him (objective vertigo) or that he himself is moving in space (subjective vertigo). True vertigo is always the result of a disturbance of the nervous mechanism involved in the maintenance of normal body balance. Dizziness has a much wider connotation and is frequently a *forme fruste* of syncope. The question suggests that the symptoms in this case are properly called dizziness and that they are related to change in posture. Tests should be carried out to determine whether there is a fall in blood pressure and an increase in pulse rate on rising from recumbency. Nocturnal polyuria and aggravation of symptoms in hot weather would also suggest the possibility of orthostatic hypotension. The symptoms of this condition may be relieved by elevating the head of the bed about eighteen inches. This is accomplished by placing the posts of the head of the bed on ordinary kitchen chairs. Patients sleep comfortably in this position, though some may need a hard pillow under the mattress at the level of the thighs to prevent slipping. Pooling of blood in varicose veins, carotid sinus syncope (ruled out by pressure on the carotid sinus), and spontaneous hypoglycaemia are further possibilities. There are many other conceivable diagnoses, however, and reference should be made to Soma Weiss's review.

Nipples and Breast-feeding

Q.—The genuine desire of a mother, her nurse, and her doctor to establish breast-feeding is frequently foiled by painful, cracked, or bleeding nipples. What treatment do you advise (a) in the ante-natal period, and (b) after the birth of the child?

A.—There is no need during the ante-natal period for any special treatment to the nipples if they are normal, except daily washing with soap and water and drying with a rough towel. When the nipples are flat or depressed they should be massaged daily during the last two months of pregnancy with vaseline, lanoline, or witch-hazel cream. Treatment during lactation is essentially prophylactic. The nipples need to be washed night and morning with soap and water. It is important that the mother should wash her hands before putting the baby to the breast. After feeding a sterile piece of gauze tissue should be placed over the nipples and supported by a well-fitting brassiere. Once a crack develops, feeding from the affected side should be stopped temporarily and one of the sulphonamide ointments applied.

Sternal Puncture in Typhoid

Q.—What is the value of, and what are the indications for, sternal puncture in a case of suspected typhoid fever?

A.—It has lately been shown that in enteric fever the typhoid bacillus can be isolated from sternal marrow not only in the acute stage but also for some time after it has disappeared from the peripheral blood, and that the paratyphoid bacillus may be isolated from the bone marrow of recovered cases in association with

formation in the soft tissues.² Sternal puncture is not a procedure to be lightly undertaken, and would be indicated in a case of suspected typhoid only when other methods—blood culture, examination of faeces, and Vidal reaction—had failed to establish a diagnosis. It is not sufficiently known that with modern selective culture media the infecting organism can be isolated from the faeces in most cases of paratyphoid in the first week of infection, and this probably holds good for typhoid too. In typhoid, particularly, the organism may be recovered from blood clot even in the second and third weeks of infection, so that the separated clot from blood sent for Vidal reaction should always be cultured. Sternal puncture may in certain special circumstances be justified for the detection of chronic typhoid carriers.

Transfusion into Bone Marrow

Q.—On Jan. 10, 1942 (p. 48), you published an annotation on the administration of fluids into the bone marrow of infants. No further reference to this question has been made. I should therefore be grateful if you could elucidate the following points: (1) Why is this method not used for more often? What is its value? (2) Could you give a detailed description of the technique? (3) Can it be used to transfuse blood into the marrow (a) of infants, and (b) of adults?

A.—The administration of fluids into the bone marrow is not used extensively at the moment for the following reasons: (1) It is not generally appreciated that fluid can be given by this route. (2) Though once learnt the technique of administration is easy, many people hesitate to begin. Its value is considerable for the following reasons: (a) It may be extremely difficult in an infant to find the veins, which are small. It is not, however, so difficult to locate either the sternum or the tibia. (b) In a patient, for instance, who is severely burnt, it is impossible to find a vein because of the local trauma. Blood, however, can be administered into the marrow cavity through a burnt area. There is no doubt that in many cases this route of administration is life-saving.

A variety of rather elaborate techniques have been described, but the principle is the same. In the case of both children and adults some sort of sedative should be given. A local anaesthetic is then applied over the site of puncture—the tibia probably in a baby, the sternum in an adult—and a needle is passed into the sternal cavity. When in place, this is filled with either normal saline or citrate solution by means of a syringe, and is then fitted to the administering unit for blood, plasma, or saline, as the case may be. In the case of an adult Salah's sternal puncture needle is convenient; in the case of a baby a strong needle of the type used for administering blood intravenously in adults is suitable.

Blood can be readily given into the marrow cavity of infants and adults, and is in fact often administered by this route by those experienced in the technique.

Fusosporillosis

Q.—Epidemic ulcerative stomatitis recurs in an institution for healthy homeless children wherever previous cases are readmitted from isolation hospitals. Readmissions may relapse into ulceration; most show merely gingivitis, sometimes very limited. Organisms resembling Vincent's are found in healthy mouths. Should isolation hospitals therefore retain hostels of stomatitis until gums become clinically normal, which often takes months? And what can be tried for the hostel population besides ascorbic acid, nicotinic acid, individual towels and dishes, and dental and oral hygiene?

A.—Ulcerative stomatitis is an infective condition of diverse aetiology. The primary infection with the virus of herpes labialis occurs in children as an ulcerative (aphthous) stomatitis, and is undoubtedly infectious. It is probably spread directly by droplet as well as by mediate means, and would be very difficult to control in a residential children's home. Ulcerative stomatitis in Vincent's organisms are present in large numbers (some injured and live report on a properly taken smear is essential). Some would be of as infectious, but requires certain predisposing conditions. Poor dental hygiene is probably the most important. Unless he sends a report on the edentulous individuals the risk of missing occasional diet to maintain healthy gums resulting misfortunes; and if he is valuable prophylaxis. In the interest of the Services he occur in winter and the possibility of an occasional mistake is resistance is lowered. In practice, catastrophes are rare, and they occur after the fullest examination in this as in other cases.

A high case

There is little doubt that this type of dyspepsia has increased rapidly in civilian life in recent years, and is not inconsistent with routine employment with occasional absences. The question of its relation to the increase of peptic ulcer has scarcely

that the child will carry infection back to the home. Rather, the conditions for the spread of stomatitis are probably already present among the hostel population.

Low Body Temperature

Q.—To what degree is a low temperature compatible with life or fitness? I had a special thermometer made for a post-influenzal patient, aged 40. She was often doing the housework with a temperature of 91° F. although she said she felt the cold! Once, when she was down to 90.2° F. (I took it myself), she was cyanosed, but only slightly.

A.—Although it is well known that subnormal temperatures occur during convalescence after many febrile illnesses, and in cases of myxoedema and congestive heart failure, most of our knowledge of the effects of cold on the human body comes from the recent refrigeration studies in cases of carcinoma and schizophrenia. Clinical studies in these cases have shown that normal cellular tissue is capable of withstanding 40° F. for prolonged periods of time without evidence of degenerative changes. The only complication encountered in these subjects after such treatment was an atypical form of circulatory failure, which usually occurred during or immediately after the period when the temperature was restored to normal. Even so, it was extremely rare. Physiological studies show that when the body temperature is reduced there is a fall in the basal metabolic rate. The heart rate tends to become slowed and the volume output is reduced, so that the blood pressure falls. These changes are reflected in the electrocardiogram, which shows abnormalities of the T waves and a prolongation of electrical systole. There is little or no alteration in the blood chemistry or rate of respiration, and no recognizable impairment of renal function.

Psoriasis of Face and Scalp

Q.—Is there any effective treatment for psoriasis of the face and scalp in a young woman? All the ordinary lines of treatment have proved of little use. The best results have been obtained by exposure to a carbon arc lamp in increasing dosage over a period of years, but even that is now losing its effect.

A.—The effects of the carbon lamp could be increased by applying an ointment such as the following:

Hydrarg. ammon. gr. x
Liq. picis carb. 3j
Ung. paraffini (B.P.C.) ad 3j

daily to the patches on the face in the intervals between the light treatments, the ointment, of course, being completely removed before each light treatment. A stronger tar ointment such as picis carb. praep. (B.P.C.) 2% in vaseline might be used instead if the first ointment did not prove strong enough. As an alternative to the light treatment, but not combined with it, a 100 r dose of x rays might be given to the affected parts of the face, perhaps twice with a fortnight's interval between doses. This might be combined with the use of the hydrarg. ammon. ointment.

Psoriasis of the scalp requires a stronger ointment such as:

Acid. salicyl. 4%
Hydrarg. ammon. 2%
Oil of cade 12%
Halden's emulsifying base to 100%

This should be rubbed into the scalp night and morning and the head shampooed about twice a week. One or two small doses of x rays such as suggested for the face may also be used on the scalp, but the x rays must not be persisted in or the hair will fall out.

Preserving Milk

None who had lived in Africa that many of formalin (liquor formaldehyde) to We have tried this with and turns quickly with the addition of formalin in any chemi- by has it

Deaths (0-1000 live)	Deaths (excluding stillbirths)	Annual death rate (per 1,000 persons living)	Live births	Annual rate per 1,000 persons living	Stillbirths	Rate per 1,000 total births (including stillborn)
5,902	758	85	197	28	41	46
17.5	27.4

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

the gastric mucosa must result. It should not be forgotten that important use of formalin is as a histological fixative: tissue exposed to it are killed and hardened. The degree of such change produced by a small addition to milk would no doubt be slight, but the possible deleterious effects of long-continued consumption of such milk can well be imagined, and fully justify the prohibition of its use.

The Injured Diabetic

Q.—In an official A.R.P. handbook, with reference to the disposal of diabetic patients from an "incident" we are advised: "the patient is uninjured and still conscious, he should be given sugared drink and sent to hospital as soon as possible. If patient is unconscious, he should on no account be given a sugared drink but must be transferred to hospital at once." What is to be done in the very likely case of the diabetic patient who is injured and still conscious?

A.—If the diabetic is uninjured and conscious, do nothing and send him home, as he is very unlikely to develop hypoglycaemia. If the diabetic is unconscious I agree that he should not be given a sugary drink, as it might get into the lungs. If facilities are available, 20 c.cm. of a 25% solution of glucose should be given into a vein to make certain that the coma is not due to hypoglycaemia; the patient should then be sent to hospital. If the diabetic is injured, deal with him like any other injured patient, as he is very unlikely to be suffering from hypoglycaemia.

War against Fleas

Q.—As in each September, fleas are now more active and numerous, but this year seems an exceptionally bad one. Many preparations formerly used for the control of dog and human fleas appear to be off the market. Pyrethrum is said to be the active ingredient in the vegetable types of powder. What is the important constituent of the mineral types, as used for animals? Are the agents, or an effective substitute, obtainable now?

A.—The best remedy for cat and dog fleas is a fine derris powder rubbed into the fur. But this, like pyrethrum, is unobtainable at present for this use. A mineral insecticide sometimes used, powdered naphthalene, which may, however, make the animal sit for a time. An alternative to powder dressings is a hot bath with a good carbolic soap used freely. The last treatment, with change of clothing, is effective for people infested with human fleas. With all types of flea attention should be paid to the breeding site, which is usually close to the sleeping place of the host. Thorough sweeping and scrubbing will clear away the larvae, and flake naphthalene can be scattered in difficult places. Human fleas, curious enough, often breed in pig-sties, and cottages are sometimes infested in this way. The treatment then is to clear the sties and spray their floors with tar oil emulsion.

LETTERS, NOTES, ETC.

Inflammability of Trichlorethylene

Dr. C. LANGTON HEWER writes: In a paper read in May before the Anaesthetic Section of the Royal Society of Medicine I stated that "trichlorethylene vapour will not burn or explode if mixed in any proportion with air, oxygen, or nitrous oxide." It appeared from research work recently carried out by the Bureau of Mines, Pittsburgh, U.S.A., that this statement is only true if the temperature does not exceed 25.5° C. (78° F.). At higher temperatures, the drug is mixed with air enriched with oxygen or with pure oxygen, inflammable mixtures can under certain conditions be obtained. So far as I know there are no data relative to the inflammability of nitrous oxide-oxygen-trichlorethylene mixtures at high temperatures, but the matter is being thoroughly investigated by I.C.I. Ltd. Pending the publication of this report, it would seem wise to use trileane and air mixtures only, if there is any risk of a source of ignition coming into contact with the anaesthetic gases.

Prevention of Midge Bites

Dr. H. M. DENHOLM-YOUNG (Farningham, Kent) writes: Give an average-sized adult one dose of ephedrine hydrochloride gr. and there will be no midge bites (or at least no sensation of bite and no lumps) for about 2 weeks. Be sure that the blood pressure is not high, because this causes one night of misery even in a normal adult—a feeling of intense excitement.

Correction

The second sentence of the news item on the employment of nurses (Oct. 2, p. 440) should read: "Employers will not be able to employ a nurse except through an appointments office unless she has an exemption certificate." It may be added that the issue of these certificates to employers (hospital and local authority) is the subject of a Bill of the Ministry of Labour which is now in the House of Commons and will be finally made.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 16 1943

PEPTIC ULCER AND DYSPESIA IN THE ARMY

BY

SIR HENRY TIDY, K.B.E., D.M., F.R.C.P.

Hon. Major-General, A.M.S.

This communication is principally concerned with peptic ulcer, but some reference will be made to other forms of dyspepsia met with in the Army. For reasons of security statistics cannot always be given in a strictly comparable form. The types of dyspepsia occurring in the Service may be classified as follows (Tidy, 1941): (1) Peptic ulcer. (2) Gastritis and functional dyspepsia. (3) Transient dyspepsia. (4) Miscellaneous group, including such conditions as dyspepsia due to or associated with pathological changes in the gall-bladder and appendix, duodenal diverticula, and carcinoma of the stomach: the number in the Army has been very small.

Transient Dyspepsia

This type tends to develop in new recruits before they are hardened to Army routine: possibly it is less common now than earlier in the war. These men are in the main successfully dealt with in the units. It is most important that they should not be sent to hospitals or to specialists—procedures which are apt to convert a transient into a chronic dyspeptic, and finally into a useless soldier.

Gastritis and Functional Dyspepsia

No satisfactory or accepted nomenclature has been evolved for this group. "Gastritis" is now being used with a technical meaning by gastroscopists, and will probably need to be reserved for this. "Functional" tends to suggest psychoneurosis. This should not be the sole meaning of "functional dyspepsia," which refers to a disturbance of the functions in the absence of recognizable anatomical changes or demonstrable disease in the stomach and duodenum and elsewhere in the body.

Graham and Kerr in 1941 found a history of symptoms dating from civilian life in 80%, with an average duration of 7 years, most of the cases being collected in 1940. I am indebted to several officers for statistics of admissions in 1942, the averages being: age 32½, service 2½ years, duration of symptoms 5½ years, onset in civilian life 75%.

Careful studies have been made of this group in several hospitals without any definite result. Gastroscopy reveals a small proportion of organic gastritis. I do not feel satisfied at present that clinical syndromes can be connected with different types of gastritis so diagnosed, in spite of statements to this effect. It would appear that gastroscopy has not yet sufficiently established the limits of variation of a normal gastric mucous membrane or the interpretation and clinical significance of variations judged to be abnormal.

Radiological studies of the mucous membrane leave an unsatisfactory position. This applies especially to the diagnosis of "duodenitis," a term which is used with widely different meanings and interpretations by various observers. Arguments based on changes in the gastric mucous membrane are not valid for the duodenum, as is illustrated by the absence of neoplastic changes in the latter. That some form of chronic duodenitis may exist can scarcely be doubted, but evidence of its nature and interpretation and clinical signi-

ficance is absent. Duodenitis at present is a radiographical conception without clinical, surgical, or pathological support, and without agreement among radiologists. Dogmatic diagnoses and conclusions are unjustified on present evidence and should not be unreservedly accepted. The diagnosis duodenitis would appear to be used by some radiologists in conditions in which they are uncertain whether or not ulceration has occurred.

Of these cases of "functional dyspepsia" some are organic in the sense of disturbance of function, some are essentially psychoneurotic, and some others are made so.

Symptoms in this group are far more resistant to treatment than are those of ulcers, and cases need much longer in hospital for "cure" or alleviation; the longer the period in hospital the shorter is the interval to the next recurrence. There should be no attempt to retain a man in hospital in order to effect a "cure" which wide experience has shown is quickly followed by relapse on returning to duty. As soon as investigations have proved the absence of organic changes, which should be within 10 days, these men should be returned to their units. Nor should they be placed on "light duty" or "light diet." The unit is the proper authority to decide by observation if a man can be usefully retained in his unit or in his category.

Under Service conditions, and probably also in civilian life, prolonged investigations and minute inquiries tend to produce or increase a psychoneurotic factor, and a man rapidly progresses to the state of being useless as a soldier. A hospital consequently should reduce its investigations to a minimum and not aim at a standard full investigation. Gastroscopy should be restricted to those circumstances in which it has already proved its value in civilian life—e.g., for the decision as to the presence of a neoplasm or the presence of an ulcer radiologically doubtful. In the Services it should not be used for the identification and classification of gastritis. Nevertheless once a man is sent to hospital some investigation, clinical or otherwise, is inevitable. It is therefore advisable that this type should not be sent for either in-patient or out-patient investigation, or for report by a medical specialist, without definite reasons. The least of these procedures will magnify the disorder and their repetition render it incurable.

The M.O. of the unit thus has a special responsibility in keeping these men on duty, to which many become inured and are thus saved for the Service. His examination should be of the same degree and not more minute than for comparative complaints in other systems of the body. Unless he sends a large number to hospital he runs the risk of missing occasionally an active ulcer, with resulting misfortunes; and if he is to take the responsibility in the interest of the Services he should know that the possibility of an occasional mistake is fully understood. In practice, catastrophes are rare, and they may also occur after the fullest examination in this as in other conditions.

There is little doubt that this type of dyspepsia has increased rapidly in civilian life in recent years, and is not inconsistent with routine employment with occasional absences. The question of its relation to the increase of peptic ulcer has scarcely

been considered. Like peptic ulcer, it was not prevalent in the last war among British troops.

Relative Incidence of Peptic Ulcer and Non-Ulcer Dyspepsia among Army Personnel

The distribution of dyspepsia between the chief groups among Army personnel may vary considerably in different hospitals, partly depending on the type of unit in the neighbourhood and the opinions and experience of medical officers. The following figures are official returns of diagnoses of Army personnel on discharge from all hospitals in Britain for a certain period in the latter half of 1941. For comparison the discharges from the Army for the same period are also included. These figures give 58% of admissions as ulcers. Newman and Payne found nearly 90% of ulcers early in 1940, but the material had largely been sifted of non-ulcer dyspepsia in France. Of 2,500 hospital cases which I analysed (Tidy, 1941), ulcers formed 52%.

	Total Cases	Gastric Ulcer	Duodenal Ulcer	Non-Ulcer Dyspepsia
		Cases	Cases	Cases
Discharged from hospital ..	2,851	453 (16%)	1,194 (42%)	1,204 (42%)
Discharged from the Army ..	2,149	460	1,620	69

Discharges from the Army for non-ulcer dyspepsia are negligible compared with the number in hospital, and this supports the opinion that such men can make useful soldiers in spite of their handicap. No physician would suggest as an explanation of the small number of discharges from the Army for non-ulcer dyspepsia that the hospital treatment effected a complete cure. It has, however, occurred that such men, though useless and a handicap to a unit, are retained in the

poor cooking in the Army. Newman and Payne (1940), working under a grant from the Royal College of Physicians, established two facts: first, that the cases so diagnosed were in general definitely ulcers; and, secondly, that nearly 90% of the cases, both ulcer and non-ulcer, had a long history of similar symptoms in civilian life. They were of the opinion that Army cooking, and especially the greasiness of the food was a factor in causing the early breakdown and recurrence of symptoms in the Army. A large proportion of the Army at that period consisted of reservists, many of whom had been several years in civilian life, and it was anticipated that as these were weeded out the incidence of dyspepsia would fall especially if Army cooking improved. Events have disproved these anticipations. Army cooking had many difficulties to face in early days, but it has long since been of a satisfactory standard, and the number of reservists has fallen to a small fraction of the present Army. Nevertheless, the flow of both ulcer and non-ulcer dyspepsia continued.

In the last war neither peptic ulcer nor dyspepsia of other types formed a problem of any magnitude, and indeed the rarity of peptic ulcer was definitely noted and duodenal ulcer is not even mentioned in the *Medical History of the War*. So far as Army diet and cooking are concerned, there is no reason to suppose that they were better than in the present war. The relative incidence in the two wars can be judged by the following figures. In the last war up to the end of 1915 (*Medical History of the War*, 1931) the discharges from the Army for "inflammation and ulceration of the stomach" were 709. In the present war the number discharged for peptic ulcer to Dec., 1941, was 23,574.

In order to obtain a picture of the present position of peptic ulcer in the Army 800 Army medical cards (A.F.I. 1220) have been analysed; they were taken at random from the first four

TABLE I.—Analysis of 800 Army Medical Cards of Peptic Ulcer (Random Selection from Military Hospitals in Britain; Early 1942)

Onset of Symptoms	Total				Under 40 Years				Average Age		Duration of Symptoms

Service owing to the disinclination of medical boards to discharge men under this diagnosis, and that discharge ultimately is effected after reference to a psychiatrist has resulted in a diagnosis of psychoneurosis.

Some subjects of non-ulcer dyspepsia are unfit for medical service on account of their disability: the decision should be best made by those who have had the advantage of prolonged observation. Medical boards have to meet the difficulty in a practical manner without too many rules to help or hamper them, for it is certain that a loose acceptance of the diagnosis of non-ulcer dyspepsia as an invaliding disability is inadvisable.

Peptic Ulcer in the Army

The large number of admissions to hospital of men diagnosed as suffering from peptic ulcer and from non-organic dyspepsia attracted attention as early as Oct., 1939, and took the medical profession by surprise. The different circumstances which led to admission to hospital in Service and civilian life were not at first understood: but, even allowing for this, the medical profession had not recognized the extent to which dyspepsia had increased among males during the last 20 years, and believed that the influx was purely a Service development.

Two suggestions early and repeatedly made were, first, that the cases diagnosed as peptic ulcer were not in fact ulcers; and, secondly, that the prevalence of dyspepsia was due to

months of 1942 (Table I). These come from all parts of Britain, but not from over-seas.

Onset in Civilian Life and in the Army.—In 81% symptoms began in civilian life. In 19% symptoms began in the Army after the outbreak of war, the average length of war service in this group being two years, the age 30 years 9 months, and the duration of symptoms 9 months. These records for the Army and the records for St. Thomas's Hospital 1933-6 have both been analysed for men under 40 years of age to ascertain in what proportion the duration of symptoms was less than 3 years, corresponding roughly to the maximum of war service. For the Army the proportion was 26% and for St. Thomas's 35% (Army, 148 out of 553; S.T.H., 49 out of 140). These records are not contemporary, but, so far as the figures are of value, they are against any undue development of peptic ulcer during war service. Unfortunately there are no data on which one may decide if the Army incidence is higher or lower than would develop in civilian life as distinct from hospital admissions in the same age group and in the same length of time. For gastric ulcer the onset in civilian life is 73%, the previous duration of symptoms 5 years 6 months, and the average age on admission 32 years. For duodenal ulcer the onset in civilian life is 82%, the previous duration of symptoms 5 years 7 months, and the average age on admission 31 years 11 months.

Site of Gastric Ulcer.—Of 118 cases (omitting admissions for perforation and haemorrhage) the ulcer was on the lesser curvature in 90 with a 'previous' duration of symptoms of 6 years 1 month and age on admission of 32½ years, and at the pylorus in 28 with a previous duration of 5½ years and age of 29½. It is possible that pyloric ulcers early tend to produce symptoms.

The main supply of peptic ulcer in the Army is still the recurrence of symptoms which started in civilian life. The position is similar for non-ulcer dyspepsia.

Relative Incidence of Gastric and Duodenal Ulcer

The following data bear on their relative incidence in the Army:

	G.U.	D.U.	Ratio D.U. to G.U.
1. Discharges from the Army for peptic ulcer for a considerable period in later months in 1941	1,088	4,000	3.6 : 1
2. Discharges of men from hospitals over a period in 1941	453	1,194	2.6 : 1
3. Discharges from the Army during the same period as No. 2	460	1,620	3.5 : 1
4. Discharges of men from hospitals over a partly different period	1,176	2,431	2.1 : 1
5. Analysis of 800 A.F.I. 1220 diagnoses on discharge from hospitals (early 1942)	144	656	4.6 : 1
6. Analysis of 2,500 discharges for all forms of dyspepsia from a few selected hospitals (1940) (Tidy, 1941)	230	812	3.5 : 1

Nos. 1, 2, 3, and 4 are from official returns of the Army Medical Statistical Department. No. 5 is from my analysis of 800 medical cards taken at random and supplied by the Statistical Department. No. 6 is from returns of a number of hospitals which I collected for the discussion at the Royal Society of Medicine. There is a definite discrepancy in the ratios of these data. Of the 800 cases analysed for No. 5, the ratio of gastric to duodenal ulcer was 1 to 5.2 with onset in civilian life and 1 to 2.9 with onset in the Army (Table I)—that is, with the shorter duration of symptoms—and the ratio thus will vary with the relative proportion of the two groups. The proportion of duodenal ulcer was higher between 20 and 30 than between 30 and 40 years, the ratios for a series being: between 20 and 30 years 1 to 5.7, between 30 and 40 years 1 to 4.6, and over 40 years 1 to 4.3. The proportion of duodenal ulcer was also higher when the previous duration was over 3 years than when it was under 3 years, the respective ratios being 1 to 5.4 and 1 to 4. During the same period as No. 2 the discharges from the Army were gastric ulcer 460 and duodenal ulcer 1,620, a ratio of 1 to 3.5, and the numbers previous to and following this period are similar.

It is possible that the discrepancy between Nos. 2 and 3 is partly due to diagnoses made by radiography on men seen as out-patients at hospitals. This would suggest that the diagnosis of duodenal ulcer is readily made on out-patients but not the diagnosis of gastric ulcer, which is certainly more difficult. It is not easy to supply a satisfactory explanation.

The figures given for discharges from the Army (No. 1) are probably the best guide to the general relative incidence, as the numbers are large, include the whole Army at home, and are the most carefully authenticated. Discharges of officers alone give the same ratio—viz., 3.7 to 1. The Army is partly a selected personnel in relation to peptic ulcer, since many cases are rejected by the medical boards.

Liability to Relapses and Recurrences from Peptic Ulcer in the Army

When the question of peptic ulcer in the Army originally came under consideration the opinions were often expressed, first, that ulcers formed rapidly in the Army, and, secondly, that relapses and recurrences were more frequent than in civilian life. It has already been shown that the evidence is against the first statement. With regard to relapses and recurrences, it must be borne in mind that a man in the Army with peptic ulcer who develops even mild symptoms will almost inevitably reach hospital. Admissions to hospital in the Army which count as recurrences are paralleled in civilian life by periods off duty for sickness in a large industrial concern rather than by admissions to hospital. The study of peptic

ulcer among employees of the Post Office by Bashford and Scott (1935) showed the frequency of such absences even at a period when peptic ulcer was less common than nowadays.

It is probable that a man with peptic ulcer in the Services is most affected not by irregularity of the times of the principal meals, or even, within limits, by the diet, but by difficulty in obtaining food at short intervals and directly he feels that he requires it. I believe that an additional factor is that physical fitness and healthy exercise engender a large appetite. One hears from a man who knew that he had had an ulcer, and was anxious to carry on in spite of some recurrence of symptoms, that he would eat an amount at dinner which he would not think of taking in civilian life, and cover it with a liberal supply of sauce. This explains the frequency of vomiting, often at the end or, distressingly, even before the end of dinner.

Relapses in the Army will probably occur more readily than in many civilian occupations, but the incidence in the Army as compared with civilian life cannot be measured by admissions to hospital or the number of discharges from the Service. A modern investigation on the lines of Bashford and Scott's (1935) study of Post Office employees would possibly afford the best guide to the relative frequency of recurrence in the Army and civilian life.

Disposal of Cases of Peptic Ulcer

The policy of the Army is to invalid from the Service all men with the accepted diagnosis of peptic ulcer, with exceptions in the case of key men. In the early period of the war certain hospitals returned cases to ordinary duty after treatment, and this consistently proved unsuccessful. The number of cases is so large that many suggestions have been made for retaining men in the Service in some suitable role, varying from special "ulcer battalions" to "light duty"—a form of duty which, when prolonged, results usually in a negligible output. It is the experience of industry that subjects of peptic ulcer are frequently absent for sickness even when the inducement is to remain at work and the occupation allows some latitude in routine.

The Army would need to arrange not only special diet for an ulcer unit but also a special routine for times of meals—more difficult, and in my opinion equally important—and the unit would need to be undisturbed by a high rate of sickness. For if a man with an accepted ulcer reported sick with a statement of recurrence of symptoms the M.O. could rarely avoid sending him off duty. No existing unit or category in the Army meets these requirements on a large scale, and it may be doubted if any formation would pay a dividend, but conditions may be different in other Services.

Accurate diagnosis is important, for a diagnosis of peptic ulcer, once accepted, is permanent. The diagnosis nowadays rests too largely on the opinion of radiologists, not all of whom have had enough experience of the alimentary canal; and, further, a doubtful radiological opinion is not infrequently accepted as conclusive by a physician who is himself doubtful on clinical grounds. I believe that at times cases which are at least doubtful both radiologically and clinically are being given the definite diagnosis of peptic ulcer.

The position must not be regarded too strictly from the point of view of a gastric specialist. The essential duty of a medical board is to decide if a man will make a "useful soldier" in any category, and the Board must in general be guided by the reports before it. It can decide more easily when the diagnosis is within the covers of the officially accepted *Nomenclature of Diseases* of the Royal College of Physicians, which was designed for a different purpose, but it hesitates to discharge a man for "chronic dyspepsia, no organic changes" or "query peptic ulcer." The medical officer who is satisfied that such a man is useless as a soldier inclines towards a definite diagnosis of "peptic ulcer" or, with the necessary assistance of a psychiatrist, "psychoneurosis." I do not believe that the Army is thus losing many useful men because of gastric disabilities, though a certain number are spoilt by excessive investigation, attention, and treatment in hospitals. The position with regard to statistics is more intricate, and the figures for duodenal ulcer and for gastric neurosis should be accepted with some caution.

Incidence of Complications

The rarity of complications of peptic ulcer in the Army has aroused comment. It is a question if this is not more apparent than real. There are several factors which can make for an apparent rarity. First, the large number of admissions of ulcer cases for slight disturbances reduces the proportion of complications and gives an appearance of rarity. Such admissions occur especially among old-standing cases, and the returns from St. Thomas's Hospital show that complications are less frequent when the previous history is over three years than in recent cases. Secondly, 86% of Army admissions are under 40 years of age, an age group in which deaths from complications are rare.

Figures of complications for St. Thomas's Hospital and the Army are placed together in Table II. Perforations compared

St. Thomas's Hospital: 1933-6. Males						
Over 3 years	104	18	17	7	7	2 (perforation)
Under 3 years	104	29	28	12	12	2 ..
Total ..	208	47	23	19	9	4

with cases admitted are 23% for St. Thomas's and 4% for the Army. The difference may depend partly on the standard for admission of cases, which will affect the percentages, and partly on selection by the recruiting boards, since the difference in incidence is most pronounced in cases with a short history. In comparison with perforations, haemorrhages are higher in the Army than for St. Thomas's Hospital, but in the latter an admission is recorded as haemorrhage only when this is of considerable severity, and the same standard is not necessarily employed in Army diagnosis. It is clear that these two sets of figures are not comparable.

It is not impossible that the Army figures give the more correct picture of the incidence of perforation among peptic ulcer in this age-and-sex group of the population than the records of admissions to St. Thomas's, even though a number of cases of established ulcer have previously been eliminated by the medical examining boards.

Perforation of an ulcer, as is well known, may take place without previous symptoms, but in reading through the notes of cases at St. Thomas's Hospital one is struck by the number of instances in which there is a history of severe gastric symptoms for a few days or a week or so preceding the catastrophe and shock of perforation, either as a new development or with a previous history of ulcer or dyspepsia. In the Army, men would be in hospital before the intervening period elapsed, and perforation may thus be saved in a certain number of cases.

Deaths from Perforation.—The analyses of perforations at St. Thomas's Hospital have shown that the case mortality for perforations varies greatly with the age, especially for gastric ulcer. For gastric ulcer the case mortality over and under 40 years is respectively 35% and 5%, and for duodenal ulcer 19% and 14%. In the series of 800 Army medical cards there were 13 perforations with no deaths ascribed to gastric ulcer among 125 admissions under 40 years, and 17 perforations with two deaths ascribed to duodenal ulcer among 572 admissions.

Haemorrhage.—From the 800 Army medical cards, 26 men appear to have been admitted specifically for haemorrhage, with one death. All were under 40 years. Without wishing to stress the fact, it may be mentioned that the death occurred in the only instance in which operation was undertaken for the direct purpose of checking haemorrhage. The bleeding-point was found and successfully ligatured, and the operation satisfactorily concluded, but the patient died from pulmonary thrombosis.

It is probable that the incidence of perforation and haemorrhage in peptic ulcer in the Army is about the same as similar group of a civilian population, perhaps with some deduction owing to earlier admission to hospital. It is possible to make a rough comparison of deaths from perforation in the Army and in the civil population from the following data.

1. Registrar-General's Returns of Deaths. In 1938 the death per million living from peptic ulcer of males between ages 20 and years was 22.

2. St. Thomas's Hospital statistics ascribe 50% of deaths in pit in this group to perforation.

3. For the Army, data exist for the ration strength, the proportion under 40 years of age, the number of discharges from hospital for peptic ulcer in a year, and the deaths from perforation in a random sample.

The data from the Army cannot be given, and the number of deaths from perforation is too small to be reliable, the figures available suggest that deaths from perforation in the Forces are about 75% of the expected number. This figure cannot be considered as more than an approximation, but what it is worth it suggests that rarity of perforation is not apparent than real.

Other Complications, etc.—Among 144 cases of gastric ulcer there were 2 cases of previous perforation and 2 in which gastrectomy had been performed. Among 656 cases of duodenal ulcers there were 30 cases of previous perforation and 13 in which gastro-enterostomy had been performed. 7 cases were admitted with pyloric obstruction and 4 with duodenal diverticula.

Dyspepsia among A.T.S. Personnel

The number of cases of dyspepsia, organic and non-organic among A.T.S. personnel has been so small that no elaborate analysis would be of value. The comparative incidence of dyspepsia among males and females in the Army can be calculated as follows: the equivalent annual ratio per thousand calculated from the number of hospital admissions and ration strength separately for the male personnel and A.T.S. personnel. The comparison of these two values, which cannot be recorded, gives a ratio of males to females of 4 to 1. The ratio of males to females under 40 years in admissions to St. Thomas's Hospital for the period 1933-6 was 5 to 1, the distribution of the population of London between the sexes being approximately equal. As the ratio of the sexes in this period was the same for gastric ulcer and duodenal ulcer the ratio in other areas are less likely to vary greatly from this figure.

The close agreement between the ratios for St. Thomas's and for the Army indicates that the incidence in the two series is the same in the Army as in civilian life. For non-organic dyspepsia the ratio of male to female in the Army on the same basis is 2.2 to 1.

Summary and Conclusions

The incidence of dyspepsia of all types in the war of 1914-18 was low.

The prevalence of dyspepsia, organic and non-organic, in the Army in the present war is a reflex of its incidence in the civilian population, which has greatly increased in the last 20 years.

There is no evidence of undue development of fresh cases of peptic ulcer in the Army.

Of admissions to hospital for peptic ulcer in 1942, the onset occurred in civilian life in 81%—73% for gastric ulcer and 82% for duodenal ulcer. Of admissions for non-peptic ulcer, the onset occurred in civilian life in 75%.

The number admitted to hospital for minor symptoms in the Army gives an exaggerated picture of the prevalence compared with civilians.

Symptoms due to pre-existing peptic ulcer tend to recur in the Army owing to unavoidable routine, and will do so under the best conditions of diet and cooking.

Of admissions to hospital for dyspepsia, peptic ulcer formed 58% and non-ulcer dyspepsia 42%.

The ratio gastric ulcer to duodenal ulcer varies in different series but is probably about 1 to 3.6. The proportion of duodenal ulcer is higher in the age group 20-30 than in 30-40 years (which agrees with the results at St. Thomas's Hospital), and higher with a previous duration over 3 than under 3 years.

The average age of 656 cases of duodenal ulcer was 31 years, 11 months, and previous duration of symptoms 5 years 7 months. Of 144 cases of gastric ulcer the age was 32 years and duration

years. Of 118 cases of gastric ulcer, 90 were on the lesser curvature, the age being 32½ years and duration 6 years 1 month; and at the pylorus, the age being 29½ and duration 5½ years.

Men suffering from peptic ulcer are not suitable for Army life under present conditions.

Men suffering from non-organic dyspepsia can in many cases do useful soldiers provided they are not detained too long in hospital. Cure of symptoms should not be attempted. An excess of medical attention and investigation results in exaggeration of symptoms and repeated admission to hospital.

Complications are rare in the Army compared with the incidence among admissions of the same age-and-sex groups in civilian hospitals, but the rarity is more apparent than real. It is probable that the incidence in the Army is a truer reflex of the incidence in the population than is afforded by civilian hospital admissions.

The low mortality from perforation and haemorrhage is similar to that in civilian males under 40 years of age.

The comparative incidence of dyspepsia between the two sexes in the Army is similar to that among civilians.

I am indebted to Lieut.-Gen. Sir A. Hood, K.C.B., Director-General of Army Medical Services, for permission to make use of Army statistics, and to Major C. Cassidy, R.A.M.C., and Sergeant Stalbow, R.A.M.C., of the Army Medical Statistical Department, for much assistance with the records.

Medical Officer of Health, Glossop

AND

JOHN F. WILKINSON, M.Sc., Ph.D., M.D., F.R.C.P.
Director of the Department of Clinical Investigation and Research,
Royal Infirmary and University of Manchester

During the period Oct., 1941, to July, 1942 (37 weeks), he effects on the physical condition of feeding supplementary vitamin preparations to the school-children of Glossop had been investigated under a scheme devised by the Ministry of Health, and consequently we took the opportunity of using these same children in order to estimate the state of their vitamin A and C nutrition and the effects of any deficiencies on their physical condition. About 400 children, aged 9 to 14 years, were involved—200 having vitamin capsules, and 200 not receiving supplementary vitamins acting as controls; the former group (hereafter called the "vitamin group") received daily doses of 4,000 I.U. of vitamin A, 350 I.U. of vitamin B complex, 1,000 I.U. of vitamin C, 600 I.U. of vitamin D, 2 mg. of riboflavin, and 20 mg. of nicotinamide five times weekly; the latter group (hereafter called the "control group") received capsules not containing any vitamins. The present report is a preliminary consideration of the period 1941-2.

I. LEVEL OF VITAMIN C IN GLOSSOP SCHOOL-CHILDREN

Methods Employed

(a) The saturation test employed follows the method of Harris and Abbasy (1937). Test doses of 11 mg. per kg. of body weight were given in the morning, and the urine was collected during the fifth and sixth hours, acidified, and titrated against dichlorophenolindophenol. The advantage of this method is its

simplicity, especially if one is concerned with school-children, as in our case. Harris (1942) has dealt extensively with the criticisms of this method.

(b) *Estimation of the Vitamin in Blood.*—As a supplementary to the saturation test and as an essential to Part III of this paper, blood vitamin C estimations were regarded as necessary. The analysis was done on whole blood, following the method of v. Eekelen (1937) with the use of mercury acetate and hydrogen sulphide. Our findings are in agreement with those of Heinemann (1941), who discussed the value of this method fully. We do not consider it to be less informative than the method employed by Butler and Cushman (1940), who determined the ascorbic acid content of whole blood colorimetrically. In our opinion these methods are the most reliable indication of the vitamin C level in an individual. Measurable amounts of ascorbic acid are found in whole blood after the plasma level has become zero, and the fluctuation of the plasma values also influences considerably the reading in normal and saturated persons (Portnoy and Wilkinson, 1938). Analysis of the white-cell and platelet layer was carried out when severe deficiency was suspected, since the white-cell layer provides evidence of deficiency only and not of good nutrition. In the case of a deficiency, however, it has the advantage over whole-blood estimations that the results are independent of the plasma fluctuations, and the ascorbic acid appears to be retained longer in that layer than in other blood constituents. In following this routine, when sufficient blood was available, we estimated the content of the white-cell layer in cases of severe deficiency as indicated by a blood vitamin C estimation below 0.3 mg./100 ml.

(c) *Inquiry into the Dietary Intake.*—A comprehensive dietary survey covering a period of three weeks was made on the families whose children were concerned in this study. The parents kept an accurate daily record, on printed forms, of all the food used during this period, both purchased and grown in their own allotments. They were interviewed by us at the beginning and end of this period, so that the reports obtained may be regarded as reliable. We also estimated the amount of ascorbic acid and calculated the nutrients contained in the school meals during this time, thus obtaining a very detailed evidence of the dietary intake of the children. Under this heading our findings are given with regard to the vitamin C intake.

Procedure and Results

Since the combined investigations carried out on the school-children by the Ministry of Health and ourselves were of a very complex nature, and the tests were not allowed to interfere with each other, we had to choose what, in our opinion, were the most suitable methods available. Therefore, in Jan.-Feb., 1942 (three months after the beginning of the test period), all the 400 children were given two test doses of ascorbic acid and no more. This enabled us to assess the amount of non-saturation present at that time. The children in the vitamin group (200) had by then received 3,000 mg. each on an average. They were all found to be saturated, as indicated by an urinary excretion of 0.8 mg. or over per kg. of body-weight.

The control group (200) showed non-saturation in 72% of cases (145). Half of this number (71; 35%) showed no increase whatsoever, whereas the remaining 37% (74) excreted 0.3 to 0.7 mg. per kg. during the test period. The tests were continued in June, 1942 (at the end of the test period), with the object of ascertaining the severity of the deficiency. We assumed that those who in January and February had responded to the test doses with either saturation or increased excretion were not likely to be severely deficient in June. We therefore continued the tests with only the 35% of the boys who had shown no increased excretion at all. Samples of their blood were examined, and they were given test doses until full saturation was achieved. Out of these 71 boys 58 were found to be in a very deficient state—i.e., 36 having a blood value below 0.3 mg./100 ml. and requiring 5 to 7 test doses before saturation was attained, the remaining 22 a value between 0.3 and 0.5 mg./100 ml. and requiring 4 to 6 test doses for saturation. There is admittedly a good chance that some of the remaining subjects who were not investigated in June had become deficient, but their deficiency is not likely to be as

high as that of those examined. We analysed the white-cell layer in 11 cases of severe deficiency; the results obtained ranged from 3.5 to 11.3 mg./100 ml.

The dietary intake of vitamin C was calculated. Only 25% of the cases investigated showed a daily intake of over 30 mg.; 35% showed between 15 and 30 mg., and the remaining 40% under 15 mg. It must be emphasized that these figures are concerned with the period April-July only, but certainly this represents an extremely low intake.

Summary of Results

The extent of non-saturation was 72% in the control group. In the vitamin group all subjects were found to be saturated three months after the beginning of the test period. The most severe cases (58 in all) out of a group of 200 showed the following: 36 below 0.3 mg./100 ml. blood and requiring 5 to 7 test doses for saturation, 22 between 0.3 and 0.5 mg./100 ml., and requiring 4 to 6 test doses for saturation. For reasons explained in the text, it will be seen that the latter figure of 22 is probably higher. The vitamin C intake in the diet from April to June was under 15 mg. daily in 40% and between 15 and 30 mg. in 35% of all cases.

Although the level of vitamin C nutrition varied on the whole according to the social standard, there was a relatively large amount of severe deficiency present. Glossop children compared very badly with some school-children in other areas in which similar investigations have been carried out.

II. LEVEL OF VITAMIN A NUTRITION

The purpose of this part of the investigation was, first, to obtain some more evidence about the value of the dark-adaptation test; secondly, to discover if there was any correlation between the dark-adaptation test and the dietary intake; and, finally, to determine the incidence and degree of vitamin A deficiency in Glossop.

Methods and Procedure

(a) *The Dark-adaptation Test.*—The apparatus used was that described by Yudkin (1941a). As test object horizontal and vertical devices only were used, which were considered sufficient to exclude "guessing." When using these lines rather than the direction of arrows we obtained more constant and somewhat lower thresholds. We chose for our readings two parts of the curve—i.e., the final rod threshold and a field in the macular part of the curve. The former was determined after the subjects had been in complete darkness for at least 30 minutes. The latter we obtained by measuring the time required to attain a value of 6.5 μ l (logarithm of the threshold intensities expressed in micro-microlamberts) after an illumination of two minutes. As Dow and Steven (1941) have pointed out, this "recovery-time" test has many disadvantages as compared with the determination of the rod plateau; therefore reliance was placed only on "significant" changes in the cone values if they agreed with corresponding final rod changes. Although this occurred in over half of the cases, we are not of the opinion that any accuracy is gained by employing cone readings.

Our criterion of vitamin A deficiency, as indicated by the dark-adaptation test, was a vitamin A lability of the final rod plateau, as proposed by Steven and Wald (1941). The "control range" was determined in over 900 school-children after adequate supplementation with vitamin A. In 98% of cases the values obtained ranged from 2.8 to 3.4 log units. The remaining 2%, above 3.4 log units, were found to show a gradual slope when the percentage was plotted against the final threshold. The term "normal range," which appears so many times in the literature, has in most cases been employed incorrectly, and, in any case, is rather confusing. The process of dark-adaptation depends on many subjective factors, in connexion with perception and interpretation of visual stimuli, besides the various factors influencing light transmission. An assessment, therefore, of a borderline between "normal" and "subnormal" is futile unless limited to the object for which the test is being used. Since the determination of "normal" and "subnormal" thresholds is of no advantage for the purpose of testing for vitamin A deficiency, no attempt has been made to define these values. All that is required is to determine the individual variation and the "control" range, with special regard to its lower values. These findings will indicate the number of subjects within the lower limits of the control range who are not likely to improve above the individual variation

and therefore can be eliminated from further tests. All the other subjects must be given vitamin A treatment if deficient cases are not to be missed.

The variation of an individual was found to be 0.1 to 0.2 log unit during the same day and 0.1 to 0.4 unit over a period of 14 days. The latter high variation—values of 0.4 occurring in 20 out of 900 cases—must be taken into consideration when vitamin A therapy is given over a period of several days and when the significance of changes due to this therapy is being assessed. In the light of these variations all the subjects found to have initial rod plateaux of 3.1 μ l or over were subjected to vitamin A therapy after having had three tests in all.

Following the recommendation of Yudkin (1941b) the tested subjects were given at least 1,000,000 I.U. of vitamin A before the final tests were carried out, and the latter were performed 24 hours after a dose of 100,000 I.U. so that at least transient improvement would occur. The same conditions obtained in the determination of the "control range."

(b) *Calculation of the Dietary Intake.*—As part of our food survey the vitamin A intake of the test subjects was calculated. The method of this investigation is described elsewhere.

It should be added that the estimation of vitamin A in blood could not be made. Although our experiments did not show that the concentration of vitamin A in blood could be indicative of vitamin A deficiency, the comparison of the blood values with the results found by means of the dark-adaptation test and the dietary intake would have been of great value. However, taking blood from 400 children was impracticable.

Results

Adaptometer Readings.—(a) Comparison of adaptometer readings between the vitamin group and the control group before vitamin A therapy showed that the mean rod plateau was slightly but not significantly higher in the "control" group. (b) The following decreases in threshold were found after vitamin A therapy:

	0.5 Log Unit or Over	0.4 Log Unit	0.3 Log Unit
Vitamin group (200) ..	0 (0%)	3 (1.5%)	22 (11%)
Control group (200) ..	33 (16%)	14 (7%)	28 (15%)

Dietary Intake.—The intake was calculated in I.U. per kg. of body weight, and is given in percentages of the test population:

I.U. per kg.	%
Less than 20 ..	7
20-30 ..	20
30-40 ..	16
40-50 ..	12
Over 50 ..	45

Correlation of the Dark-adaptation Test and Dietary Intake.—The only definite correlation observed was that the subjects with a threshold lability of 0.5 log unit or over were in all but three cases found to have an intake of less than 30 I.U. per kg. The exceptions had an intake of 33, 48, and 60 I.U. per kg. respectively. Various subjects with a threshold lability of 0.4 log unit and many subjects with a lability of 0.3 log unit showed a really high intake. Also many cases with a very low dietary intake showed a vitamin-A-stable threshold.

Conclusions

The following conclusions may be drawn from our experiments:

1. *Criticism of the Dark-adaptation Test.*—Certain weaknesses are apparent: (i) A test based upon subjective evidence is not very satisfactory. (ii) The test is cumbersome: in order not to miss deficient cases it is necessary to administer over 1,000,000 I.U. of vitamin A to a large proportion of subjects. (iii) Vitamin-A-labile values of the order of 0.3 and 0.4 log unit can be interpreted either as being the range of individual variation or as being due to a vitamin A deficiency. Since the amount of vitamin A lability is not related to the severity of the deficiency, this is a serious disadvantage. On the other hand, a vitamin A lability of 0.5 log unit or over seems to be a definite indication of a vitamin A deficiency. In spite of the above-mentioned weaknesses, therefore, we regard the criterion of threshold lability as the best test now available for the detection of vitamin A deficiency, with the understanding that a positive result only is reliable and that various readings may be of doubtful diagnostic significance.

Concluding from our results regarding the individual variations and the correlation of the dark-adaptation test and the dietary intake, we regard a threshold liability of 0.5 log unit or over as indicative of vitamin A deficiency, of 0.4 log unit as a probable case of deficiency, and of 0.3 log unit as a possible deficiency.

2. *Incidence and Degree of Vitamin A Deficiency in Glossop.*—By means of the dark-adaptation test we found 16% deficient, 7% probably deficient, and 15% possibly deficient. The dietary intake was less than 20 I.U. per kg. in 7%, 20–30 I.U. per kg. in 20%, and over 50 I.U. per kg. in nearly half the cases.

3. *Vitamin A Requirement.*—A dietary intake of 30 I.U. per kg. and over can perhaps be described as the minimal daily requirement in children aged 9 to 14 to prevent impairment of night vision (as indicated by a threshold liability of 0.5 or over). This does not imply that an intake of less than 30 I.U. necessarily brings on an impaired night vision.

III. EFFECTS OF VITAMIN A AND C DEFICIENCIES ON THE PHYSICAL CONDITION OF THE SCHOOL-CHILDREN

In order to determine the effects of vitamin deficiencies on the physical condition of these children evidence was collected with reference to rate of growth (weight and height), strength, endurance, medical defects, incidence of gingivitis, serum complement titre, incidence of infection, and phosphatase content of plasma. For this purpose the following groups were compared:

Group A.—19–30 boys from the control group with vitamin A deficiency. All the subjects had a threshold liability of 0.5 log unit or over, and their dietary intake was in each case under 30 I.U. per kg.

Group C.—24–36 boys from the control group with severe vitamin C deficiency. All these boys had blood values below 0.3 mg. per 100 ml. and required 5 to 7 test doses for saturation. In 11 cases the vitamin C concentration in the white-cell layer was estimated; the values ranged between 3.5 and 11.3 mg. per 100 ml. Their dietary intake was under 20 mg. in all cases.

Group AC.—14 boys with combined vitamin A and C deficiencies.

Group O.—30–50 boys from the vitamin group. They were shown to be on an adequate vitamin A level and to be saturated with vitamin C. In comparing growth, strength, and endurance it was noticed that there was a difference in initial weight between the A and C groups. It was therefore considered advantageous to have two O groups—one of 36 boys and one of 50 boys, corresponding in weight to the A group and the C group respectively—so that there would be no significant difference in initial weight between the groups compared.

In assessing differences in this inquiry the following formula was used to obtain the statistical "T" figure:

$$T = \frac{\bar{x}_1 - \bar{x}_2 + \sqrt{\frac{1}{N}}}{\sqrt{S(x_1^2) - \frac{(\sum x_1)^2}{N_1} - S(x_2^2) - \frac{(\sum x_2)^2}{N_2}}}$$

Where $\bar{x}_1 - \bar{x}_2$ = means; x_1 the one set of variables and x_2 the other set; N_1 = the number of one set of variables and N_2 = the number of the other; S = summation and $\sqrt{\frac{1}{N}}$ = value of $\sqrt{\frac{N_1 + N_2}{N_1 \times N_2 (N_1 + N_2 - 2)}}$, to be obtained from tables according to number of variables. (Mr. H. C. Stone, B.Sc., kindly helped to work out some of the data.)

Dietary Intake

Before these groups were compared it was important to calculate their intake of animal protein, vegetable protein, total protein, fat, and carbohydrates in order to discover if there was a significant difference in the dietary intake of the groups which might account for any difference found. This evidence was obtained from the family budgets plus the amount of food received by the children at school (milk and other school meals). It was considered best to calculate the heat value of the food as purchased for the individual families, to deduct 5% for waste in housekeeping, and to add to this amount the school meals, after which the intake per man-value was calculated. The physiologically utilizable portion of nutrients and calories was not calculated, since loss in absorption is equal in both groups. In working out the vitamin content of the diet we used the tables given by Fixsen and Roscoe (1937–8, 1939–40).

Results.—No significant differences were found between the mean values of the protein, carbohydrate, and fat intake in

the groups compared. It may be assumed, therefore, that the groups differ only with regard to their vitamin intake in that the vitamin group had the additional capsules whereas the control group lived on the basic diet. The full analysis of the family budgets will be given in a separate report.

Interval.—The interval was 36.7 ± 0.078 weeks.

Ages			
Groups	Means	Standard Deviation	
O (36)	10.680 \pm 0.257	1.543	
A (20)	10.970 \pm 0.258	1.068	
C (24)	11.159 \pm 0.172	0.854	
AC (14)	11.170 \pm 0.358	1.342	

There were no significant differences between the groups in age.

Growth

The growth was worked out as percentage gains in 36.7 weeks of the test:

1. Weight

Groups	Initial Mean Weight in lb.	S.D.	Percentage Mean Gains in lb.	S.D.
O (36)	67.35 \pm 1.358	8.149	5.890 \pm 0.550	3.300
A (20)	67.00 \pm 2.464	10.750	4.427 \pm 0.324	1.649
O (50)	73.68 \pm 1.897	13.410	6.740 \pm 0.574	3.760
C (24)	72.24 \pm 4.680	12.040	6.676 \pm 0.875	4.290
AC (14)	73.26 \pm 4.820	18.060	5.500 \pm 0.895	3.148

There was a significant difference (as indicated by the T figure being over 2) between O (36) and A (20)—in other words, there was a significant difference in percentage gains of weight between the group deficient in vitamin A and the saturated group, the A group gaining significantly less in weight than the O group. No other significant differences were found.

2. Height

Groups	Initial Height		Percentage Gains in Height	S.D.
	Initial Mean Height in Ins.	S.D.		
O (36)	53.43 \pm 0.774	5.864	2.63 \pm 0.134	0.807
C (24)	54.75 \pm 0.878	4.304	2.65 \pm 0.185	0.903
A (20)	54.65 \pm 0.716	3.415	2.49 \pm 0.171	0.773
AC (14)	55.50 \pm 1.020	3.830	2.52 \pm 0.303	1.135

There were no significant differences in percentage gains in height, the T figure being under 2.

Endurance (Fatigue-resistance Potential)

The endurance was tested in terms of the time in seconds that the test subjects could hold themselves suspended on a horizontal bar.* The following comparisons are made:

1. Comparison of Groups Individually at Beginning and End of Test; also Comparison among Groups at Beginning of Test

Groups	Performance in Seconds		Differences
	Beginning of Test	End of Test	
O (36)	116.50	116.2	0.30
O (50)	116.06	112.2	3.86
C (24)	116.60	92.7	23.90
A (19)	127.00	107.4	19.60
AC (14)	125.30	91.1	34.20

Result.—The performance of the C and AC groups was significantly worse at the end of the test after 36.7 weeks as compared with the beginning.

2. Comparison between Groups at End of Test

Groups Compared	Difference in Seconds on Bar	T Figure
O (36) + C (24)	23.50	3.80
O (50) + C (24)	23.20	2.22
O (36) + A (19)	19.25	1.79
O (50) + A (19)	15.50	1.70
O (36) + AC (14)	34.20	2.79
O (50) + AC (14)	30.30	2.65

There was no significant difference between the groups at the beginning of the test.

* The time represents the fatigue-resistance potential per lb. of body weight as per formula $\frac{1}{2}MV^2 \times t$, in which $\frac{1}{2}V^2$ is constant (see Milligan and Lewis-Fanning, 1942; Milligan, 1943).

Result.—At the end of the test there were significant differences between the O and C groups and also between the O and AC groups, the performance of the C and AC groups being significantly worse.

3. Comparison of the Total Fatigue-resistance Potentials between the Groups

(The F.R.P.-figure = $\frac{1}{2}MV^2 \times t$, and represents the total energy.)

Groups Compared	Differences in Average Percentage Gains or Losses	T Figure
O (36) + C (24)	27.89	3.13
O (50) + C (24)	24.28	2.70
O (36) + A (19)	23.00	2.15
O (36) + AC (14)	29.66	2.38
O (50) + AC (14)	26.10	2.24

Result.—All groups as compared with the O group showed a significant decrease in the total energy figures.

N.B.—With regard to the A group the low rate of gain in weight would partly be responsible for the low energy figure (see elsewhere in paper).

Strength

The strength was tested by pulling on a dynamometer, and the results were worked out as gross pull in pounds divided by body weight.

Result.—No significant differences in strength were found between any of the groups compared.

Effect of Massive Doses of Vitamin C on Physical Efficiency

In dealing with strength and endurance, in addition to the "long-term" effect of vitamin A, a test was made of its "short-term" effect. At the termination of the official test time, massive doses of vitamin C were given to the vitamin-deficient boys; the results were noted by examination before the doses were given and immediately after the children were found to be saturated with the vitamin.

1. Strength

	Mean Pull in lb. Before Saturation with Vitamin C	Mean Pull in lb. After Saturation with Vitamin C	T Figure
C cases ..	165.46	180	1.07
AC cases ..	169	172	0.19

2. Endurance

	Mean Time on Bar Before Saturation with Vitamin C (Seconds)	Mean Time on Bar After Saturation with Vitamin C (Seconds)	T Figure
C cases ..	88	99	0.88
AC cases ..	94	88	0.43

The massive doses of vitamin C to saturation produced no significant results either in strength or in endurance. The short-term effects of vitamin C appear to be different from the long-term effects.

Incidence of Gingivitis

Method of Examination.—Miss P. Nicholls, L.D.S., kindly compared 36 cases of the C group with 36 cases of the O group at the beginning and the end of the test. Data were taken from the upper and lower incisor regions only. The fact that temporary teeth were retained or premolars erupting in a large number of cases made it necessary to exclude the back portion of the mouth. A detailed statement of the oral condition was made on each examination. The location of the inflammation was noted, also prophylaxis, irregularities, delayed eruption of teeth, cavities, etc. The conditions were classified into acute, subacute, and chronic; and the gums were described as "clear" if no signs of hyperaemia or hyperplasia were observed.

Results

	Groups	Clear	Acute	Subacute	Chronic	Total
Beginning of test (Oct., 1941)	C	7	22	6	1	36
	O	8	20	6	2	36
End of test (July, 1942)	C	16	9	7	4	36
	O	18	13	2	3	36

There was no significant difference in the incidence of gingivitis between the two groups, but it will be noted that the occurrence of gingivitis decreased remarkably in both groups at the end of the test as compared with the beginning.

The Serum Complement Titre

The serum complement has been shown to consist of many fractions, but it is nevertheless interesting to find that it has been reported to have very low values in scurvy. The purpose of this investigation was to discover if there was any decrease in the complement titre in subscorbutic cases.

The estimation of complement is difficult, but one of the best methods is that of Ecker *et al.* (1938), in which the end-point is taken when haemolysis first begins. Dr. F. Stratton kindly estimated these, employing essentially Ecker's method.

The serum complement of the C and O groups (each group consisting of 30 children) was estimated. No significant differences were observed between the two groups, and no substantially low values were found in the deficient group. In view of the immunological importance attached to the complementary property of serum, and the few conditions in which it has been shown to be diminished in titre, these observations indicate that complete exhaustion of the vitamin may be necessary, as in scorbutic conditions, before complement titre is significantly reduced. This should not, however, be taken to indicate that additional therapy with vitamin C is unnecessary in deficient cases, as these observations show nothing concerning the continued sustenance of a high-titre complementary property under continuing unfavourable dietetic conditions and a supervision of infection.

Incidence of Infection

A survey has been made with regard to the incidence of infection in each of the groups. Twenty-five subjects of groups O, A, and C were compared. A list was first obtained of all the boys who had been absent from school for more than two days. Subsequently the children's parents were interviewed and an allowance was made for non-relevant factors such as broken legs, etc.

Results

Groups	Mean Absences	S.D.
O	1.68 ± 1.110	5.550
A	5.96 ± 0.990	4.990
C	4.76 ± 1.265	6.318

A significant difference was found in the incidence of infection both between O and A groups ($T=3.14$) and between O and C groups ($T=2.40$).

Medical Defects

The assessment of physical defects is not an easy undertaking and allowance must be made for errors, so that it must be frankly said that great accuracy is not possible. There were, however, certain conditions that could be assessed with more confidence than others, such as various skin conditions (acne, boils, other sepsis, chilblains), glands (enlarged tonsillar glands), lungs (cough and rales), and cheilosis. Only these conditions were assessed.

Results.—(1) Examination at beginning of test (Oct., 1941): No significant differences existed between any of the groups compared. (2) Examination in March, 1942: Significantly more defects were found in the A and AC groups as compared with the O group. (3) Examination at end of test (July, 1942): No significant differences were found between any of the groups. Our impression, however, during the examinations in March and July was that the skins of the O group were clearer, smoother, and sleeker than in the other groups. Similar observations were made by Wilkins and Rollason (1937).

Phosphatase Content of Plasma

When taking blood samples of the O and C groups for the determination of the vitamin C content and the complement titre, the estimation of the phosphatase content in the plasma was carried out with a view to detecting early bone changes in cases of avitaminosis. We employed the micromethod described by King *et al.* (1937), which measures the amount of phenol liberated from phenylphosphate when incubated at 37° C.

Result.—There was no significant difference between the two groups, and no substantial increases were noted in the C group. We wish to thank the head teachers and staff of the Glossop schools, the parents of children, the Health Department staff, and various voluntary technicians for their co-operation, which made this investigation possible. We also are indebted to Messrs. Organon Laboratories, Messrs. Roche Products Ltd., and Messrs. Glaxo Ltd. for generous supplies of the vitamins.

AGE INCIDENCE AND PROGNOSIS OF EPILEPSY

BY

F. J. NATTRASS, M.D., F.R.C.P.

Professor of Medicine, University of Durham; Physician, Royal Victoria Infirmary, Newcastle-upon-Tyne

In the course of some 20 years' experience of epilepsy in hospital and private practice I have been impressed by the number of cases of epilepsy of unknown origin beginning in middle and later life. While all writers recognize that idiopathic epilepsy may arise at any age, an onset in later life is generally thought to be rare. Organic disease of the brain which may cause epilepsy is commoner in later life, and therefore epilepsy in such patients is more likely to be a symptom of progressive intracranial disease than in children or adolescents. A statement such as the following, taken from the latest edition of Osler's *Medicine* (Christian, 1942), is typical: "It is well always to be suspicious of 'epilepsy' beginning in adult life, for in a majority of such cases the disease is not epilepsy" (italics mine).

Some statements, however, are much more dogmatic. For example, Penfield and Erickson (1941), in their recent book *Epilepsy*, which is a very fine study of the surgical aspects of the problem, lay great stress on the age of onset of fits as a factor in diagnosis, though they are careful to state that idiopathic epilepsy may occur at any age. They say:

"In cases of onset of seizures between 35 and 55, the most frequent cause is cerebral neoplasm" (italics mine). "After 55 years the various cerebral lesions produced by abnormality of the cerebral blood vessels become more frequent, though the strong probability of neoplasm must still be remembered." And lastly: "Idiopathic epilepsy comes on in youth, not in early infancy, and not in middle age or old age."

Age of Onset

As such statements did not correspond with my experience, I instituted, with the aid of Flight Lieut. H. G. Miller, formerly medical registrar, and Dr. Frank Robertson, first assistant, an inquiry into the age of onset in my cases, and, secondly, into the cause of attacks in the later age groups.

TABLE I.—Age of Onset of Epilepsy: Present Investigation

Age (Years)	Private	Hospital	Total
0-10	20 (22%)	83 (22%)	133 (22%)
11-20	56 (58%)	122 (32%)	185 (31%)
21-30	49 (51%)	82 (22%)	131 (22%)
31-40	28 (12%)	44 (12%)	72 (12%)
Over 40	41 (17%)	40 (11%)	81 (13%)
Total	231	371	602

The cases number 602. The private cases cover a period of 18 years, hospital cases 12 years; hospital out-patient records before this time were removed for salvage without my know-

ledge. No cases seen during the past two years have been included, as insufficient time has elapsed to judge of their outcome. A study of the figures will reveal that there is a general correspondence between the private and hospital groups, and that of the whole series 25% showed the first evidences of epilepsy after the age of 30 and 13% after the age of 40. The group of 81 patients with onset of attacks over the age of 40 were chosen for special follow-up.

Table II shows a comparison with previous records of the age of onset of epilepsy. While all the records show the

TABLE II.—Age of Onset of Epilepsy: Comparison with Previous Records

Age (Years)	Gowers (1,450 Cases)	Turner (1,033 Cases)	Nattrass (602 Cases)
0-10	29%	31.3%	22%
11-20	46%	46.7%	31%
21-30	15.7%	12.7%	22%
31-40	6.4%	5.8%	13%
Over 40	3.3%	4.6%	13%

highest incidence in the second decade, the figures of these eminent observers (Gowers, 1901; Turner, 1907) indicate only 9 to 10% of patients in whom the first fits occurred after the age of 30, as compared with 25% in my series.

Results of a Follow-up

Table III summarizes the results of a follow-up of the 81 patients who developed attacks diagnosed as epilepsy with onset after the age of 40, and in whom at the time of initial examination no cause could be found for the attacks.

TABLE III.—81 Cases diagnosed Epilepsy of Unknown Origin with the First Attack after the Age of 40

Untraced	24
Deaths	16
Tumour proved	5
G.P.I.	1
Cerebral arteriosclerosis	1
Heart failure	1
Air raid	1
Pancreatic tumour, ? hypoparathyroidism	1
Unknown	3
Living and traced	41

The number of untraced patients (24) is perhaps not surprising considering the years involved in the inquiry. The 41 patients living and traced were nearly all re-examined; of the few who could not attend adequate information was obtained. The present condition of these 41 patients is indicated in Table IV.

TABLE IV.—Present Condition of 41 Traced Patients of the Series in Table III

3 patients have had only 1 fit:	
11 years ago, at age 53	
7 " " " 55	
6 " " " 43	
1 patient had 2 fits at age 47, now aged 54	
6 others have had no fits for the past 9 years (2 cases), 5 years (1 case), 5 years (1 case), 2 years (2 cases)	
The remainder continue to have fits at very variable intervals	

In some cases the frequency of fits remains unchanged, but on the whole there seems a tendency to diminution in the frequency and severity of attacks with the passing years. None of these patients shows any symptom or sign of intracranial tumour. Their general condition on the whole is good; most of them are living almost normal lives and are at work. For example, one patient is the manager of a large branch of an insurance company though he is the subject of major seizures and has very severe myoclonic twitching from time to time between attacks. Another patient had 7 major nocturnal attacks between the ages of 67 and 77, when they ceased. He is now aged 83, and is exceptionally well.

With regard to evidence of cerebral arteriosclerosis, a moderate degree of hypertension is found in a proportion of cases (Table V).

TABLE V.—Incidence of Hypertension (41 Cases re-examined)

B.P. in one patient	= 210/120
B.P. " " "	= 190/130
B.P. " " "	= 190/100
B.P. " " "	= 195/95
B.P. " " "	= 180/100 (Attacks ceased since 1935)

Hypertension seems to us to occur in no greater proportion in these patients than in non-epileptic subjects of the same age, and the height of the blood pressure has not been found to

bear any relation to the frequency of fits. Blood pressure in these patients has shown little variation since the onset of their fits. Other evidences of cerebral arteriosclerosis—for example, strokes and mental deterioration—are notably absent. Only one case showed marked mental changes when he first came under observation; this condition improved with the response of the fits to treatment, and the man has been back at work for some years.

Jacksonian Epilepsy

The question arises whether Jacksonian epilepsy is especially suggestive of tumour. Among the total of 81 patients with onset over the age of 40, 7 are known to have had Jacksonian attacks (Table VI). Of these, 6 are dead, the cause being shown.

TABLE VI.—Significance of Jacksonian Epilepsy among 81 Patients

Number known to have Jacksonian attacks	7
Dead	6
Cerebral arteriosclerosis	2
G.P.I.	1
Heart failure	2
Unknown cause	1

The mortality rate is probably exceptional, but the point which emerges is that Jacksonian attacks, while revealing the site of the disturbance, give no indication of the nature of the lesion.

Time of Epileptic Attack

A last point of clinical significance is the time of epileptic attacks. Among the 41 surviving patients of the last group the time of attack was: nocturnal only, 13; diurnal only, 16; irregular, 12. The purely nocturnal incidence of attacks has two important advantages: first, such attacks, occurring in bed, are unassociated with danger of injury, and the patient is able to lead an ordinary life by day; secondly, there is a better chance of controlling nocturnal attacks by maximum doses of an anti-epileptic remedy given at night.

Summary and Conclusions

The age of onset of epilepsy is considered in a series of 602 cases.

81 patients in whom epileptic attacks began after the age of 40 were followed up, and the results of the inquiry are recorded.

Making full allowance for errors in diagnosis, it is clear that the majority of these patients who began to have fits after the age of 40 could not be the subjects of cerebral tumour, severe cerebral arteriosclerosis, G.P.I., or other progressive disease. Most of them continue to have epileptic attacks from time to time without other evidences of disease.

These observations provide no contribution towards the aetiology of idiopathic epilepsy, but they suggest some conclusions which may be of practical value: (1) According to my experience idiopathic epilepsy is by no means uncommon in persons of mature years. (2) Though fits may be the first symptom of intracranial tumour it is rare for them to precede all other symptoms and signs by months or years. (3) In the later years of life epilepsy has remarkably little effect on intellectual powers and general health.

I am interested in this matter from the point of view of teaching. I would suggest that students should be advised always to regard epilepsy as a symptom and to search for the cause both in the nervous system and elsewhere; and, secondly, to try to discover the site of the disturbance by careful analysis of the aura or earliest stage of the fit; but that these rules should apply to epilepsy at any age, and we should not stress unduly the incidence of progressive disease as a cause of epilepsy in the later years of life.

THE SCOPE OF PREVENTION IN OPHTHALMOLOGY

BY

IDA MANN, D.Sc., F.R.C.S.

(Nuffield Laboratory of Ophthalmology, Oxford)

The recent publication by Marshall and Seiler* of the statistical analysis of 3,219 persons certified blind during 1923 raises the question of the preventive function of ophthalmology. There is at the present time a total of 74,000 blind persons in England and Wales whose maintenance costs the State £4,500,000 annually, while practically nothing is spent on planned prevention of blindness by improved facilities of treatment, by education of the public, or by research.

Marshall and Seiler's figures bring out certain noteworthy points. First, the seven most important causes of blindness are, in order of occurrence:

Cataract	16.77%	of the total examined
Myopia	16.34%	" "
Venereal disease	13.95%	" "
Uveitis	10.72%	" "
Glaucoma	8.69%	" "
Congenital anomalies and abiotrophics	7.45%	" "
Injuries	6.42%	" "

Secondly, although at first sight the first four items would suggest that the greatest amount of blindness occurs in older age groups and does not therefore carry so great economic importance, yet actually only half the cases began blind after 50, and in two-thirds of these the underlying cause had started before that age. In view of the longer expectancy of life now than formerly, and the increasing average age of the population in general, as well as of workers in responsible positions, it is obvious that most of the causes of blindness begin to operate early enough to constitute a risk of economic importance. Thirdly, the relatively low percentage of blindness from injury appears surprising until we realize two points: namely, that the position of injury in the list of causes varies between 10.3 and 5.8%, according to whether the first or the second eye, or both, are involved; also, most serious industrial eye injuries lead to loss of one eye rather than both, only those of great severity such as explosions and fires leading to blindness. Injuries appearing to any extent in statistics of blindness, the time lost from injuries short of this order is of great economic importance.

Although, because of the certification of blind persons for the payment of pensions to the blind, statistics are readily available, what we lack is a precise knowledge of the amount of working-time lost and of inefficiency and disability caused by eye injuries and diseases which do not end in blindness but which nevertheless should be, if possible, reduced in number. Even if the condition does end in blindness there is a latent period of illness and steadily increasing disability during which the patient is unable to work. This is brought out by Marshall and Seiler's tables, which show the average times between the onset of the cause of blindness and the actual certification. In some cases it is considerable: for example, in all accidents the difference between the age of onset and the mean age of blindness is 3.11 years; in glaucoma it is 2.94, in cataract 5.1, and in inflammatory conditions it is higher still (e.g., trachoma 25.58, and uveitis 15.15, while it is highest in myopia (36.24 years). Quite apart from these figures exists the mass of time lost from accidents which prevent recovery and from accidents leading to the loss of one eye only, which never come to certification. As pointed out by these authors, these must be borne in mind as explaining the surprisingly low figures for blindness as a result of injury. It is to be emphasized that in any discussion on prevention the non-blinding conditions must be taken into account.

When we consider the list of conditions involved from the point of view of possible reduction of eye disease it becomes obvious that advances could occur mainly in three directions:

* Marshall, John, and Seiler, H. E. (1942). *Brit. J. Ophthalmol.* 337, 385, 434.

namely, by improvement of the ophthalmic services of the country, by education of the public on ophthalmic matters, and by further research into aetiology and therapeutics.

Improvement of the Ophthalmic Services of the Country

From certain of Marshall and Seiler's figures it would appear that some relation exists between the number of blind, specially in the higher age groups, and the hospital facilities of the district. This is to be expected, and could only be countered by making modern ophthalmic hospital treatment equally available for everyone. This would entail geographical planning and co-ordination on a regional basis, together with the provision of a larger number of ophthalmic surgeons than are at present available. Some more standardized system of training for ophthalmologists at recognized centres and a reconsideration of the requisite examination standards would be advisable, as, at present, postgraduate teaching is somewhat haphazard and there is no uniformity of qualifications demanded by hospitals in various parts of the country. Thus the problem is linked with those of regional planning and of medical education. In addition, the vast questions of ophthalmic benefit and the relations between approved societies, ophthalmic surgeons, hospitals, and opticians would also appear to be involved. There is need, too, for a closer supervision and better facilities for diagnosis and treatment of children under school age and of adolescents leaving school but not yet eligible for ophthalmic benefit. At present no provision is made for these groups, and much preventive work might be done on them.

Education of the Public

This is a basic factor in maintaining the national health. One has only to consider the chaos which exists in the public mind on such subjects as the difference between a refractive error and a disease (and, through this, between an optician and an oculist), the value and nature of orthoptic exercises, and the relation between the condition of the eye and the general health, to realize that much could be done by clearing up misconceptions alone. It is well known that many people with glaucoma postpone medical treatment beyond the limit of safety by buying stronger glasses as a makeshift, and that practically all amblyopic eyes in children are due to the belief of parents that the child will outgrow the squint and that young children should not wear glasses. So little is known of the anatomy and physiology of the eye that it is usually difficult to explain to patients such simple problems as the nature of myopia and of cataract. This ignorance paves the way for the development of ocular neuroses and the accompanying vogue for magical or much-advertised systems of treatment. That these are successful in many cases points to the need for a higher standard of diagnosis among ophthalmologists and a higher level of educated co-operation from the patients. Education is needed at three levels. Some biological and physiological instruction in schools should be obligatory: it should include an understanding of the mechanism of sight and the nature of binocular vision and of errors of refraction. In adult life authoritative information should be available on such subjects as the care of the eyes (such as the futility of constant eye baths) and the nature of presbyopia. Most especially, however, instruction is needed on protection of the eyes in industry, since most minor injuries are due to the prevalent attitude towards safety-first measures and to ignorance of the possible effects of such injuries.

Research

The trend of medical research at the present time is towards greater collaboration between experts in different branches of science. Since medicine is largely an art there must be, for progress, close contact with the basic sciences underlying it. Advances in ophthalmology of recent years owe practically everything to basic discoveries in the realms of physics and chemistry—pharmacology and physiology also, co-operating. We have only to mention the practical application of the diathermic current and of the cathode ray, the improvement in optical glass and plastics, the synthesis of the sulphonamides, the discovery of the nature of vitamins and their biochemical action, and the researches of psychologists into

the visual function to show how closely interlocked with advances in ophthalmology are discoveries in other fields. Too often, however, the ophthalmologist, overburdened with the mass of clinical work confronting him, lacks the requisite contact with the experimental sciences. The establishment of research teams in association with laboratories where physicists, physiologists, biochemists, and pathologists, among others, could unite with ophthalmologists for the solving of given problems would seem to be desirable. For example, to return to Marshall and Seiler's report and the seven most common causes of blindness, we can foresee that the problems of cataract and glaucoma will require the help of biochemistry for their solution and that uveitis must invoke experimentation in pathology, bacteriology, and immunology. Venereal disease is already yielding to chemotherapy, and myopia and the abiotrophies probably require genetical research for their unravelling. The question of injury includes experiments in the design of protective goggles and work on the best psychological approach to ensure their use.

If these desiderata be kept in mind it is possible that when the next survey of the statistical position can be undertaken a distinct improvement may be manifest.

RISE IN POTASSIUM CONCENTRATION IN THE BLOOD STREAM FOLLOWING ISCHAEMIA OF MUSCLE MASSES

BY

R. E. REWELL, M.D., M.R.C.P.

(From the Department of Pathology, Guy's Hospital Medical School)

It is well known that the concentration of potassium is much greater in cells than in tissue fluids. Thus Eichelberger (1941) found 25 times as much by weight in dog's muscle (corrected for blood and fat content) as in the serum. This great difference in potassium concentration on the two sides of the cell membrane is maintained only so long as this structure remains undamaged. Prolonged asphyxia is one method of causing such damage. Baetjer (1935) found, by measuring its concentration in the perfusate, that loss of potassium from cat's muscle increased as the rate of blood-flow was reduced, but that the actual excitability of the muscle remained unaltered. Fenn *et al.* (1939) found that there was a limit to the potassium reduction in cat's muscle that could be brought about by perfusion. Later, Fenn, Koenemann, and Sheridan (1940) observed that no increased loss of potassium or production of lactic acid followed periods of asphyxia in perfused frog's legs.

Method of Investigation

The present investigation was undertaken to determine whether or not any appreciable loss of potassium followed periods of asphyxia in the larger muscle masses of human beings. The subjects were patients to whose limbs tourniquets had been applied for periods ranging from 35 to 100 minutes in the course of orthopaedic operations. They were all muscular young adults, mostly men. Blood samples were taken from the antecubital vein just before and at seven minutes after the removal of the tourniquet. From the first few patients additional samples were taken—one at the start of the operation and another one hour after its conclusion; but since the former revealed only the usual slight fall in the concentration of potassium that occurs during the administration of an anaesthetic, and the latter a subsequent return to normal, they were soon discontinued. The clot and serum were separated as soon as possible, and any specimen with a trace of haemolysis was discarded. The potassium was estimated by the cobaltinitrite method of Tisdall and Kramer (1921), using duplicate samples and putting through a standard with each batch. In the later cases inorganic phosphate was determined

SERUM POTASSIUM AFTER MUSCLE ISCHAEMIA

BRITISH
MEDICAL JOURNAL

as well, applying the phosphomolybdate method of Denigès (1921) to the usual trichloroacetic acid filtrate. The results are shown in the accompanying table. The significance of the differences observed was calculated by the method of Fisher (1938), and a value for P of less than 0.01 was found. The rise in the serum potassium is thus statistically significant. Although marked and consistent, the observations upon the serum phosphate are too few for statistical methods to be applied.

I have to thank Mr. E. S. Jamieson for the opportunity of making these observations on his cases.

Table of Results

Case No.	Duration of Ischaemia (Mins.)	Position of Tourniquet	Serum Potassium			Serum Phosphate		
			Before Removal	7 Mins. Later	Rise	Before Removal	7 Mins. Later	Rise
1	90	Top of thigh	19.5	22.6	3.1	—	—	—
2	50	Below knee	22.2	23.6	1.4	—	—	—
3	80	Half up thigh	21.2	27.6	6.4	—	—	—
4	50	Top of thigh	18.6	21.2	2.6	—	—	—
5	70	Above knee	20.3	20.2	-0.1	4.5	5.2	0.7
6	70	Above knee	18.6	16.5	-0.6	—	—	—
7	45	Right arm	16.7	18.7	-0.2	—	—	—
8	100	Below knee	17.4	19.2	1.3	—	—	—
9	90	Above knee	17.1	19.2	2.1	5.4	7.4	2.0
10	35	Half up thigh	19.5	20.0	0.5	3.3	4.0	0.7
11	60	Top of thigh	16.9	17.7	0.8	3.8	4.8	1.0
12	60	Top of thigh	19.7	21.4	1.7	4.3	—	—

The values for the serum potassium and phosphate are in mg. per 100 c.cm.

Discussion

Houssay *et al.* (1937) found that in chloralosed dogs general asphyxia for from two to four minutes led to an increase in the serum potassium, but that this did not occur after removal of the liver or suprarenal cortex or section of the splanchnic nerves. It is to be assumed, therefore, that the potassium was released from the liver by parasympathetic stimulation. Thus in the present series there are two possible sources of the extra potassium found in the serum. It might have come either from the asphyxiated cells, presumably those of the muscles, or from the liver by the action of a hypothetical substance present in the ischaemic limb and suddenly released into the circulation—such a substance as Blalock (1930) postulated in his experiments on the production of shock. It should be noticed that in only three cases—Nos. 5, 7, and 9—was severe trauma applied to the limb during its period of ischaemia, and that these showed no exceptional rise in serum potassium, and that other operations were for the removal of semilunar cartilages, or manipulations of similar severity.

The only feature in common between this series and cases of the "crush syndrome" is the period of ischaemia undergone by the muscles. Recent observations on that condition—e.g., those by Beall, Bywaters, Belsey, and Miles (1941) and by Bywaters and Beall (1941)—have shown that a steady and prolonged rise in the serum potassium occurs. This is possibly due to the concomitant renal failure, and would certainly mask the small and transient change noted here, as also would any marked release of potassium by direct trauma to the muscle cells.

No attempt has been made to find any correlation between the duration of the asphyxia, the weight of muscle involved, and the amount of potassium released. This might shed light on the origin of the potassium, but it cannot be attempted without a larger series than the present. In this connexion it should be noted that if it could be assumed that equilibrium between the blood and the intracellular fluids of the tissues had been reached, every rise of 1 mg. % in the serum potassium would mean that 0.19 g. of the ion had been released into the circulation. The weight of the muscles of the calf and foot is about 1,300 g. (Roessle and Roulet, 1932), while the potassium content is about 0.3% (Gamble *et al.*, 1923; *Tabulae Biologicae*, 1926), so that in Case 9 of the present series the ischaemic muscle would have to give up about 10% of its potassium to account for the whole of the rise observed in the serum.

Summary

A series of observations is reported in which the serum potassium showed a significant rise after the removal of a tourniquet applied to a limb during the course of orthopaedic operations. The extra potassium in the circulation might have come from the cells in the ischaemic area or from the liver by the action of a hypothetical substance released in the limb.

Medical Memoranda

Manual Dilatation of the Pelvis: Four Further Cases

In 1936 I reported (*British Medical Journal*, 2, 282) a case in which the pelvic girdle was dilated to avoid the death of patient in parturition. On that occasion the measure was adopted as one of desperation. The result was gratifying. Since then we have made considerable use of the method as one of election, and experience has been progressively encouraging. I am now able to single out four definite cases in which we feel justified in ascribing to its use the getting of a live undamaged child from an undamaged mother. (We acknowledge its valuable help on other occasions.)

Three cases do not need a separate description. All three were primiparae; (b) had a minor degree of pelvic contraction which ante-natally justified an expectation of successful delivery (perhaps assisted), given normal opportunity for natural dilatation of the passages and moulding of the head; (c) were complicated by early rupture of the membranes; (d) required intervention on account of signs of foetal distress; and (e) required this intervention at a stage when, although labour was already more or less protracted, the size-relation of the head and passages was unfavourable.

The fourth case was that of a 1-para with marked general contraction, and properly a hospital case; she was a new-convert to the district, and an unexpected call. The membranes ruptured at the onset of labour. A good degree of moulding was allowed. When delivery was undertaken it was necessary to make full use of manipulation.

PURPOSE AND INDICATIONS

The purpose is to minimize damage to the mother, and damage, especially cerebral damage, to the child. It is meant to replace any current practice, except forceful dragging of a child through unnecessarily narrow passages. It is indicated in proportion to the expectation of difficulty. It is indicated to be indicated whenever forceps are used to overcome resistance by the bony passages to the transit of the head, and to be as rational on behalf of the child as completing the dilatation of the soft passages is on behalf of the mother.

In at least some cases of disproportion (particularly with early rupture of the membranes), when the head gets an unfavourable entry at the brim, the disproportion tends up to a certain stage to become worse. Although confident that this can occur, I feel that an attempt to analyse the mechanics of the process might bring me into one-sided conflict with the anatomist. The labour may survive this phase successfully; but if for any reason delivery has to be undertaken before the head has become adjusted to the passage, corrective measures should be addressed to the bony as to the soft passages. In the first degree this correction is, in the jargon of the moment, a "de-worsening," but some further stretching of ligaments and easing of joints are almost always attainable with comparative ease and with safety.

TECHNIQUE

The technique is essentially elastic. Leverage must be from bone to bone, and may be done with the finger-tips on one and the knuckles or the back of the hand against another, or with other. Much depends on the size of the operator's hand and other local conditions. One must ensure that bone is underneath the finger-tips, as there is usually some degree of oedema of the soft tissues, and these are easily damaged. Leverage

should be applied only for a second or two at a time, the changes being rung from one pair of points to another. The degree of pressure used is comparable to that used on a joint stiff from disuse—say an elbow which has been immobilized for some weeks. It can be more than this, but should not be much more. Firm stroking across their axis with the pulp of the finger-tip helps to stretch ligaments which are still taut. The gain may not be appreciable during the application of pressure, but becomes clear as one works round and returns, is one repeatedly does, to points already treated. A most useful increase of room for the passage of the head can be obtained without haste and without trauma in two or three minutes. When one feels that the best has been done, the hand already in the vagina guides the blade of the forceps. The anaesthesia is not significantly prolonged.

CONCLUSION

It is submitted that manual dilatation of the bony pelvis can be safely and successfully used to minimize birth trauma; that it is specially indicated in cases of slight disproportion which have to be delivered at an unfavourable stage; and that it constitutes a useful rejoinder to early rupture of the membranes.

Lochmaddy, Isle of North Uist. ALEX. J. MACLEOD, M.B., Ch.B.

Treatment of Fusospirillary Balanitis

The aetiology of this type of balanitis was proved by Corbus and Harris in 1907 to be due to the symbiosis of a Gram-negative spirochaete and fusiform bacillus, and the resulting clinical features, described in detail by them, are briefly recapitulated here.

Predisposing factors are a tight prepuce, wetting the prepuce with saliva, and unnatural sexual gratification. About 3 to 4 days after intercourse there is a feeling of irritation under the prepuce, soon followed by the appearance of a copious frothy yellow offensive discharge and superficial ulceration of the glans penis and under-surface of prepuce. Phimosis with inability to retract the prepuce may subsequently occur, but usually only develops after 8 to 14 days in the absence of treatment. The inguinal glands may be slightly enlarged but do not suppurate.

On examination, after retracting the prepuce and removing the pus, small greyish-white patches are found in the preputial area, with erosions on either side of the coronal sulcus. The edges of the ulcerated areas are often circinate in outline. Diagnosis is made by staining a smear of the pus with gentian violet or neutral red—when large numbers of spirochaetes and fusiform bacilli are seen—or, alternatively, by dark-ground illumination. Prevention, apart from circumcision when there is a tight prepuce, consists in the regular cleansing of the preputial area, especially after sexual intercourse. The condition may be treated by frequent bathing with hydrogen peroxide or other mild antiseptic. A preparation of stovarsol as a jelly (containing merfenil 1:100,000) has been tried in a series of 38 cases. The advantages of this preparation are several. It is dispensed in a small collapsible tube which can be carried by the patient in his pocket or haversack, and may be applied quickly without mess in the secrecy of the lavatory; it relieves the irritation after the first application, and is rapidly curative. It contains no sulphonamide, and therefore cannot produce sulphonamide sensitization.

In all, 38 cases have been treated with this preparation—32 as out-patients and 6 as in-patients. After washing the glans penis and subpreputial space with saline a small quantity of the ointment is squeezed from the tube and spread gently over the area. The prepuce is drawn forward and any excess wiped off. When the preparation could not be applied direct to the subpreputial areas on account of phimosis the subpreputial space was washed out with saline, and a cotton-wool-tipped probe soaked with the jelly was then passed all around under the prepuce. In most cases the ointment was applied twice daily, but in-patients were treated three times a day. The average number of applications of jelly for all cases was 5.5 (minimum 2; maximum 13) and the average number of days taken for complete healing was 3.5. Several mild infections cleared up in two days. Four cases relapsed, but were cured by further treatment.

I regard this new method of treatment as highly effective, but the independent observations of others are desired.

I wish to thank Dr. R. C. L. Batchelor for permission to study those cases in the Edinburgh Venereal Diseases Department, and to Pharmaceutical Specialities (May and Baker) Ltd. for supplies of stovarsol jelly.

Reviews

PERMEABILITY OF MEMBRANES

The Permeability of Natural Membranes. By Hugh Davson, D.Sc., and James Fredrick Darstlin, D.Sc. With a foreword by Prof. E. Newton Harvey. (Pp. 351; illustrated. 25s.) Cambridge: The University Press. 1943.

The subject of the permeability of membranes, and more particularly that of their differential permeability, is one of the most fundamental and important in the whole of biological science. It lies at the root of most of the phenomena of life in animals and in plants of all degrees of organization. The phenomena involved are primarily physico-chemical, and studies of permeability have been made by the most varied methods and upon the most diverse kinds of cells. It is no light task, therefore, to assemble and critically to review and digest the results of the numerous investigations which bear upon the subject of permeability, and to deal with the frequently abstruse physical chemistry which has been directed to the elucidation of the manifold phenomena which have emerged from those studies.

This formidable task has been very well performed by these authors, and they have produced a treatise which should serve as a loadstone for some years to all who wish to enter this perplexing territory. Much of the work discussed concerns the permeability of the red cells, which are obviously well suited for investigation. But it is made clear that what holds good for the erythrocyte cannot necessarily be transferred to other cells, or even from erythrocytes of one species to those of another. Much of this work is that of the authors themselves. The illustrations are clear, the bibliographies comprehensive, and altogether the work is a mine of carefully compiled and well-digested information. Perhaps some of the physico-chemical explanations are a little optimistic; and one would have liked to see more, if more is known, about the permeability of the lung membrane to gases. But the general impression is one of excellence.

UROLOGY IN GENERAL PRACTICE

Urology in General Practice. By Nels F. Ockerblad, B.S., M.D., F.A.C.S., and Hjalmar E. Carlson, B.S., M.D., F.A.C.S. (Pp. 383; illustrated.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co. 1943.

The preface to this book points out the desirability of stimulating an interest in and knowledge of urology among general practitioners and medical students. It was written for this purpose. Those who read the preface will expect to find something worth while in the pages which follow, and they will not be disappointed. General surgeons who have a leaning towards urology and make it their hobby (which is far better than specialization in the narrow sense) will find in this small volume a fund of practical information presented and illustrated in an attractive manner.

The authors are masters in the art of instruction. The technique of cystoscopy is described adequately in simple language. There is a good summarized account of medical ailments such as nephritis. These references are relevant and are too often omitted from surgical textbooks. The authors believe that doctors "are coming more and more to realize that the urologist knows more about the kidney and the diagnosis of its diseases than anyone else." The chapter on lithiasis is vague and is not quite up to the high standard set in other sections, but any omissions here are counterbalanced by the clear and detailed accounts given of carcinoma of the prostate, sterility, and the use of sulphonamides in urology.

There are 362 pages (excluding the index and preface) with 98 illustrations. In so confined a space some good material of necessity must be omitted. Nevertheless, the doctor who masters the contents of this book, and puts its precepts into practice, will be able to deal in an expert fashion with the majority of urological cases. His knowledge will not be confined to the commonplace, for he will find illustrations of certain rare conditions such as wide dilatation of the lower third of the ureter, without obstruction, probably congenital in origin.

A DICTIONARY OF SKIN DISEASES

Synopsis of Diseases of the Skin. By Richard L. Sutton, M.D., and Richard L. Sutton, jun., M.D. (Pp. 480; illustrated, 28s.) London: Henry Kimpton, 1942.

There is certainly a great deal compressed into a small compass in this volume, which will go conveniently into a not very capacious pocket. The authors remark that it pleases them to observe how much can be said with comparatively few words. The result is that they have produced a book which is more like a dictionary of skin disease than anything else: in fact, we rather fancy that it would be improved if any arrangement were abandoned and an alphabetical arrangement of which the authors are proud does not make for easy reading, and for that reason it is hardly suitable as a student's textbook, while as a treatise of a comprehensive character it cannot, of course, compete with the monumental works on dermatology of which the same authors' own production is a notable example. The function of the present volume lies hardly among the medical profession at all, but it would find a distinct sphere of usefulness in the world of journalism. Nowadays disease is news among the general public, and the presence of a work like this in the newspaper office or on the desk would certainly prevent many errors in those who offer to the general reader items of dermatological significance thought sufficiently spicy or dramatic to interest him. The numerous and excellent photographs with which this book is embellished will also be found very helpful.

TESTS FOR COLOUR VISION

The Series of Plates designed as Tests for Colour-Blindness. By Dr. Shinobu Ishihara, Professor of Ophthalmology, Imperial University of Tokyo. Ninth edition (complete edition). (32 plates. £2 10s.) London: H. K. Lewis and Co. 1943.

The deserved popularity of the Ishihara plates used as tests for colour vision has created a demand for this work, which is out of stock in this country and cannot now be obtained from Japan. Messrs. H. K. Lewis and Co. have shown public spirit in obtaining permission from the Patent Office to bring out a facsimile of the original to satisfy the demands of the three Services and of private practitioners, and the Chiswick Press has on the whole carried out satisfactorily a difficult task. In format and execution this facsimile is a close approximation to the original, but it must be stressed that it is only an approximation. Most of the plates in this reproduction are as serviceable as those of the original, even if some of them do not quite catch the exact shade of colouring of the original, but some few fall below standard. Plates 10, 11, 12, and 13 are more difficult to read in the facsimile than in the original, while Plates 16 and 17 are not above criticism. The examiner will have to use this reproduction with discretion if he wishes to avoid unnecessary rejections on the ground of colour blindness.

Notes on Books

Prof. WILLIAM BOYD's popular *Textbook of Pathology* has appeared in its fourth edition (Henry Kimpton; 48s.), somewhat diminished in size in spite of the introduction of much new matter. This has been achieved by omitting a chapter and several sections on subjects which are dealt with in books of other kinds, and by what the author characteristically describes as a "tightening of the belt of speech." Few medical authors make so telling a use of metaphor, or captivate their readers by presenting their subject in so engaging a style. New and up-to-date information has been introduced on a large number of subjects, among which are several that have only very recently come into prominence, and there are many new illustrations.

The second edition of *Social Service in the Clinic for Venereal Diseases*, by DOROTHY MANCHÉE, is even more welcome than the first because the problems dealt with are more insistent in wartime than in peace, and case-holding and follow-up have assumed a much greater importance since the launching of the anti-V.D. campaign and the introduction of Regulation 33B. The wartime upsets of family life and the direction of female labour into industry have introduced difficulties never dreamed of in peacetime. There can be no doubt that an almoner in every V.D. treatment centre is rapidly becoming a necessity rather than a luxury, and Miss Manchée tells us what such a lady can accomplish. The book is specially recommended, to all directors of venereal disease clinics. It is published by Baillière, Tindall and Cox at 5s.

Preparations and Appliances

BRITISH MEDICAL JOURNAL

ANAESTHETIST'S THIRD HAND

Flight Lieut. P. S. A. HEYWORTH, R.A.F.V.R., writes:

Before describing this simple piece of apparatus, shown in the accompanying sketch, it must be emphasized that (1) it may be a dangerous gadget in the hands of the occasional anaesthetist; (2) it was devised for the experienced anaesthetist working under short-handed conditions, and not to relieve him from supporting the jaw during normal times. The patient is settled so that it is possible to maintain clear airway by supporting the jaw with a finger under the chin. The cushion of the apparatus is placed under the holding finger and the direction of the force is noted. The tap

is now hooked firmly round a convenient piece of the anaesthetic apparatus and secured with a pair of forceps. If the direction of the pull is inconvenient, the position of the patient's head can, of course, be altered.

The knack of maintaining a clear airway cannot be acquired by brief training. For two years, while working with changing apparatus to handing the patient over to an unskilled assistant, I have often eliminated the necessity for an endotracheal tube and has proved invaluable when a blood or plasma transfusion has to be given by the anaesthetist and there is no one free in the theatre to support the patient's jaw. During thyroid surgery it is a pleasant relief to aching fingers if the main pull is taken by this little apparatus.

I wish to thank Air Commodore R. R. Macintosh for his help and criticism, Miss M. C. McLarty for the drawing, and Mr. R. Salt for his help in making the original holder. The instrument can be obtained from Medical and Industrial Equipment, Ltd., 12, New Cavendish Street, London, W.1.

RECENT GLAXO PRODUCTS

Glaxo Laboratories, Ltd., Greenford, Middlesex, are now introducing certain new products.

2:1-diaminoacridine hydrochloride is said to have the lowest toxicity of all the flavines; in dilutions of 1 in 1,000 it has the least effect on living tissues. It is rapidly bactericidal, and in effective concentration does not interfere with healing. It is also effective against certain Gram-negative organisms—*B. proteus*, *B. coli*, and *Ps. pyogenes*—that are not affected by other acridines in similar concentrations.

5-aminoacridine hydrochloride in dilutions of 1 in 1,000 is a non-irritant antiseptic with an antibacterial activity similar to that of other flavines against the common pyogenic organisms. It does not stain the skin and is easily removed by water from fabric.

Nicotinamide, while possessing a similar therapeutic value to nicotinic acid, has the important advantage of not producing the uncomfortable flushing and other skin reactions so common with the acid "Pelonin" amide, brand of nicotinamide, is available in tablets and in ampoules containing 50 mg.

Suspended T.A.B. Vaccine (synthetic culture medium) Glaxo physicians prefer a suspended type of T.A.B. vaccine because many antigenic properties of the organisms are retained, while the absence of protein from the culture medium restricts the reaction to that produced by the bacteria themselves.

BEHAVIOUR AND NEUROSIS

he attempt to reduce psychoneurotic reactions in human beings to terms of conditioned reflexes has been criticized before. There has been an impression in some minds that such a conception is somehow more scientific than one that includes psychological as well as physiological principles. It is therefore of all the more interest to know that in all the years of his investigations of animal behaviour Pavlov was so married to his rigidly mechanistic philosophy that, as is recorded by his pupil Frolov, he would actually impose a fine on any of his assistants who ventured to suggest that the behaviour of experimental animals might be determined largely by physiological needs, aversions, conflicts, or other internal motivations. This is hardly the spirit of science, but the bias persisted to the end of Pavlov's life. It is true that towards the end he began to look at clinical problems, but by that time he approached them inevitably backwards, as it were, with his mental vision fixed upon a picture of cortical processes. Having by then discovered, as he thought, a fundamental physical basis for the genesis and mechanism of neurotic reactions in dogs in terms of excitement and inhibition in parts of the cortex, he sought to explain the social behaviour of human beings in the same terms. He approached the whole in terms of the part and not the part in terms of the whole, which was curiously contrary to the general trend of physiological philosophy in his later years. It did not occur to him to think in terms of the meaning of the stimuli; a bell was a sound, for example, and not something that meant food or nothing, according to whether the animal wanted food or not. A neurosis was merely a conflict between excitatory and inhibitory phases in more or less of the cortex and not a struggle to solve a problem of vital importance to the animal as a whole. Although these criticisms seem more or less obvious, any effort to make them was accompanied by a sense of discomfort, because no experimental control of Pavlov's work had appeared. All the work in conditioned reflexes, or, at any rate, all that part of it that seems relevant, has been done by Pavlov's disciples, who used the same language and the same concepts. Of those signs the dog gave of responding to a stimulus because no food followed, it was said that the "threshold" response was "raised" by the stimulus. Nothing, as Masserman puts it in his recent book,¹ was said about the dog's frustration or even about his hunger.

It is particularly welcome that a book should appear which embodies experimental work on Pavlovian lines but which undertakes it from the aspect of the organism as a whole, taking into account all drives and instincts as well as localized cortical processes, and making the setting of the experiment much less artificial. The animal is not placed in complete isolation and protected from every stimulus except the experimental one. The experiment is not only with a conflict of stimuli. Masserman shows that unless the stimuli are related to the animal's needs no conditioned response can be established. Masserman made experiments also with a conflict of motives—for example,

between hunger and fear—and in this way, for the first time, a real parallel was drawn with human problems and failures to solve them. After all, the very fact of the use of the unconditioned stimulus in all Pavlov's work implied a reference to the emotional or instinctive side of life, which was never admitted. The difference in conceptual approach is between a narrow mechanistic and a biological conception. Masserman insists that motivation is an essential basis for even the most elementary Pavlovian experiment. He points out that the reaction is not to a mere stimulus; it occurs only in relation to the total apperceptive field. The dog salivates to the sound of a bell only if the sound has come to mean food and if the dog is hungry. What matters is the significance of the sound and not merely its physical conformation as a wave front impinging on a receiving apparatus. That the linkage is not solely a mechanical one between a cortical disturbance and some sort of local emotional mechanism is suggested by the failure of attempts to link the response to a pure sound stimulus with the effects of direct stimulation of the hypothalamus—e.g., with a "sham rage" reaction. No linkage between sound and rage reaction could be established in this way.

Consistent neglect of the importance of the meaning of a stimulus led Pavlov to postulate inhibition, where, for example, the response becomes extinct from lack of "reinforcement," such as lack of feeding. What really happens in such circumstances is—nothing. The animal has failed to be interested. Pavlov arrived at a specious physiology by neglect of analysis in psychological terms. We are still, as Sherrington said long ago, very far from having a physiological picture of an idea. Masserman's work is important as probably the first criticism of Pavlov's work by means of experiments based on a wider philosophy. By his method he has shown that it is possible to provide experimental analogies at least with emotional conflict in neurosis, with symbolic behaviour, with phobias and, more doubtfully, with regression, as well as with the cure of neuroses by manipulation of the environment, or, where a solution is forced on the animal, by "working through" the problem.

INTERCELLULAR HORMONES

For some years it has been known that growth-promoting factors can be obtained from plant and animal tissues and in greater amount when such tissues have been injured. The frequent speculations on the role of these factors in the processes of wound healing and in tissue overgrowth have been severely limited by the obscurity surrounding their origin and nature. Recent publications of Loofbourov and his colleagues,¹ however, have gone far to unveil the mysteries of these factors, called by him "intercellular hormones." The earliest of their publications showed that there appeared in the fluids surrounding the tissue factors which stimulated cellular proliferation when yeast, various other micro-organisms, living tissues of rat, mouse, and chicken embryos and of the adult newt are subjected to various forms of injury such as lethal ultra-violet irradiation, x rays, mechanical injury, and chemical irritation. The findings of previous workers were supported and extended. In the later papers, however, by limiting their attention to the growth factors produced by yeast cells damaged by ultra-violet light, and assaying the potency of these factors by their ability to promote the proliferation of yeast cells in Reader's solution, Loofbourov and his co-workers have made some interesting advances.

¹ *Behavior and Neurosis. An Experimental Psychoanalytic Approach to Psychobiologic Principles*, By JULES H. MASSEMAN, M.D. (18s.). Chicago: University of Chicago Press; London: Cambridge University Press. 1943.

¹ *Biochem. J.* 1940, 3, 432, 1580; 1941, 35, 603; 1942, 36, 513, 631, 737.

The first fact to be established was that these proliferation-promoting intercellular hormones were to a great extent soluble in alcohol and in acetone, largely thermostable, entirely free from proteins, and similar in many respects to "bios"—the term used to describe the body of factors required for the growth of yeast and including inositol, vitamins B₁ and B₆, β -alanine, pantothenic acid, and biotin. It was also noted that the higher the potency of the intercellular fluid the higher was its content of substances with an absorption spectrum showing a maximum at 2,600 Å, characteristic of purines and pyrimidines. Experiments were then planned to determine whether these factors were released as a result of cell disintegration or of increased cell permeability, whether the factors were largely synthesized by living injured cells and released by them into the intercellular fluids, or whether the activity of these fluids was attributable to some combination of these possibilities. It was found that slow injury yielded intercellular fluids of greater potency than did rapid killing, the potency of the fluids increasing rapidly before appreciable mortality occurred. Further, the potency was greater when cells were injured in a physiologically favourable suspension medium such as Ringer or Reader solution than when injured in distilled water or isotonic salt solution. Active factors appeared in suspensions of cells exposed to high concentrations of CO₂, though the cells were not killed. Cells killed quickly by grinding or boiling and then subjected to lethal ultra-violet light yielded less potent preparations than cells injured slowly by ultra-violet light before grinding or boiling. It thus seemed probable that the proliferation-promoting activities of the intercellular fluids were due either to the release of normal cell constituents as a result of increased membrane permeability or to the release of materials synthesized in the living cell as a response to the injury, or to both of these processes. Further observations supported and extended these possibilities. No change in cell numbers and no cytotoxicity were observed during the irradiation of cell suspension, indicating that the proliferation-promoting factors were released to the intercellular fluids through the membrane of substantially intact cells. Studies with radio-active phosphorus indicated that cell membrane permeability increased during radiation—a fact confirmed by the observation that during injury the average cell volume decreased by more than one-quarter. From these studies Loofbourow and his colleagues conclude that the production of the intercellular hormones by damaged cells is due to increased cell membrane permeability, allowing the diffusion into the surrounding fluid of various normal non-protein cell constituents and the resynthesis of some or all of these materials within the living injured cell as their concentration in the cell is disturbed by the diffusion process.

With such an interpretation of the manner in which the intercellular hormones may be produced, it was almost inevitable that attempts should be made to determine whether known growth factors could account for the proliferation-promoting effects of damaged yeast-cell suspensions. Tests with 15 amino-acids, yeast and thymus nucleic acids, inositol, thiamine, riboflavin, adenosine, and nicotinic acid, used singly, had either imperceptible activity or not enough activity to account for that of intercellular hormone preparations. When, however, some of these materials and other known growth factors were used in combination, the proliferation of yeast-cell suspension was profoundly stimulated. A mixture of thiamine, riboflavin, pyridoxine, calcium pantothenate, biotin, choline, and nicotinamide strongly stimulated the proliferation of yeast cells in Reader's solution, while the further addition of a mixture of glutamic acid, asparagine, aspartic acid, leucine, and

arginine increased this effect. The vitamins also hastened the growth of yeast in the presence of preparations from damaged and undamaged cells, the further addition of the amino-acid mixture increasing the effect still more. However, the growth kinetics with the vitamin and amino-acid supplements differed from those with the damaged cell product, and it seemed that additional factors were present in the latter. Since a correlation had already been found in damaged cell preparation between proliferation-promoting activity and the concentration of materials showing absorption spectra characteristic of purines and pyrimidines, and in particular of adenine, a number of such compounds were tested. None when used alone would produce the activity of damaged yeast, though adenosine triphosphate showed activity greater than the others. A mixture of adenosine triphosphate and the vitamin supplement was found to have a proliferation-promoting activity like that of a damaged cell preparation, while further supplementation with the amino-acids increased this activity still more. However, the amount of adenosine triphosphate required to produce this effect was about ten times the amount indicated by the intensity of absorption at 2,600 Å of the damaged yeast-cell preparation used, suggesting that adenosine triphosphate was not necessarily the purine or pyrimidine derivative partially responsible for the activity of these products.

It is extremely satisfactory research which enables a phenomenon previously shrouded in mystery and cluttered with cumbersome descriptive phrases to become explicable in terms of the behaviour of known chemical substances. Loofbourow and his collaborators have still a number of gaps to fill in the story of their "intercellular hormones," and this they will no doubt hasten to do. In the meantime however, their work should prove a valuable stimulus to studies on wound healing and tissue regeneration. Perhaps the hastening of wound healing induced by embryonic and other tissue fluids and by maggots will also become more completely explicable in terms of known chemical substances. One of the most pleasing aspects of Loofbourow's work is the clear demonstration that, while substances used alone may have no marked activity, when used together they become active. It seems that the experiments now in progress in various laboratories on vitamin C in healing processes would perhaps lead to more useful results if additional essential nutrients were taken into consideration at the same time.

INDUCED VITAMIN B₁ DEFICIENCY IN MAN

Williams and his co-workers, who have already published three studies on induced vitamin B₁ deficiency in man,^{1,2,3} have made yet another contribution to the subject.⁴ Two volunteers were given a basal diet containing not more than 0.1 mg. of vitamin B₁ per 1,000 calories daily (0.1 to 1.0 mg. per 1,000 calories daily is considered the optimum). This is much less vitamin B₁ than was given in previous studies. The diet was adequate in other respects and was supplemented with halibut-liver oil, irradiated ergosterol, ascorbic acid, riboflavin, nicotinamide, pyridoxine, pantothenic acid, choline, inositol, iron, and calcium—all known to be essential for either human or animal nutrition. Any deficiency symptoms could then be reasonably attributed to lack of vitamin B₁. The experiment lasted for 120 days, although every two weeks an injection of 1.0 mg. of vitamin B₁ was given for a "periodic partial cure" of the deficiency. Symptoms of vitamin B

¹ *Proc. Mayo Clin.*, 1939, 14, 787.

² *Arch. Intern. Med.*, 1940, 66, 785.

³ *Ibid.*, 1942, 69, 721.

⁴ *Ibid.*, 1943, 71, 38.

deficiency developed as early as the thirtieth day of restriction. The first objective evidence of abnormality was a decrease in the urinary excretion of the vitamin after a test dose of 1 mg. Almost simultaneously the pyruvic acid level in the blood after the administration of glucose became elevated, and the subjects became listless and complained of anorexia and easy fatigue. Listlessness progressed to apathy, anorexia to nausea, and fatigue to prostration, with diminished response to test doses of vitamin B₁ and with an elevation of the blood pyruvic acid. At the same time complaints of paraesthesia in the legs were made. Later objective signs of disturbances in the nervous pathways became evident, and after 110 days on the restricted diet signs and symptoms of polyneuropathy appeared. Defects in the cutaneous sensory pathways, depression or disappearance of the tendon reflexes, and paralysis of the muscles of the thighs and legs became apparent. Paralysis of muscles and loss of tendon reflexes were not observed in the earlier studies—possibly in the first study the restriction of vitamin B₁ was too severe for the experiment to be carried on over any length of time, while in the other studies the restriction was not severe enough. The disturbances responded to the administration of large doses of vitamin B₁, but only after many weeks, and in one of the cases incompletely after four months of continuous treatment. It was also noted that invariably appetite was improved and activity resumed for 7 to 10 days after the injection of the test dose. The outstanding subjective features of a pure vitamin B₁ deficiency in man would therefore appear to be anorexia, fatigue, and symptoms of polyneuropathy.

Johnson and his colleagues³ subjected ten men to hard physical work on diets deficient in parts of the B complex. Fatigue, deterioration in physical fitness, muscle pains, poor appetite, and constipation were complained of after two weeks. Vitamin B₁ alone in doses of 2 mg. daily did not clear up these symptoms, but brewer's yeast did. Similar observations were made by Egeña and others⁴ on sedentary subjects.

Interesting as these studies are, it must not be forgotten that in actual practice deficiency diseases are never limited to lack of a single factor, or even a group, such as the B vitamins. Beriberi is not caused by a deficiency of vitamin B₁ alone; it is a poly-avitaminosis. Polished rice, which is consumed in countries in which beriberi is endemic, is deficient not only in vitamin B₁, but also in vitamins A, D, and E, riboflavin, nicotinic acid, pyridoxine, choline, calcium, iron, and other minerals. Deficiency of vitamin A and members of the vitamin B complex has been shown to produce central and peripheral nerve lesions.^{5,6} It is also possible that vitamin E deficiency may play a part in the advanced muscular degeneration seen in beriberi. Another fact that may complicate the picture is that polished rice may be deficient not only in vitamins but in certain amino-acids (e.g., methionine) essential for human nutrition. The fact remains that in none of the studies on induced vitamin B₁ deficiency in man has the full-blown picture of beriberi been produced.

HOSPITAL PHYSICISTS ASSOCIATION

The inaugural meeting of the Hospital Physicists Association, held in London at the British Institute of Radiology on Sept. 24, was attended by 37 physicists drawn from hospitals all over the country. The aims of the new Association are to discuss matters arising out of the mutual

interests of those engaged in a branch of scientific work which has grown up largely in the last 30 years. Membership is open to physicists attached to hospitals, medical schools, medical or biological research departments. The first meeting was followed by visits to the Middlesex, Royal Cancer, and Westminster Hospitals on Sept. 25. The afternoon session was devoted to papers. Dr. H. T. Flint spoke on technique with the various radium gramme units, Prof. Hopwood gave an account of the betatron, Prof. Stead discussed teaching for the diplomas, and Prof. Sidney Russ read a paper on the professional equipment of a hospital physicist. Messages of good will from the National Radium Commission and the Council of the British Institute of Radiology were read at the meeting. It was agreed to hold at least three meetings during the year, one of which should be in the Provinces. Prof. Russ was elected chairman for the first year, with Dr. Wilson of Westminster Hospital acting as hon. secretary. Prof. Russ recalled that the first full-time appointment as physicist to a hospital was made 30 years ago. It seemed likely that to-day between 50 and 60 physicists were engaged in some capacity in hospital or medical research work. A good start was made with the new association, with plenty of evidence of vitality among its members.

PLANNING THE AIR ABOVE

The replanning of towns and cities will be largely frustrated if there is no planning of the air above them. One of the many good causes which has suffered a setback in the war is smoke abatement. Excessive smoke emissions from factory chimneys are now too often seen, and authority gazes at them with a blind eye. Planning for smokeless air, as the general secretary of the Smoke Abatement Society, Mr. Arnold Marsh, pointed out recently, must proceed in two phases: the first to ensure that new sources of smoke are not created in post-war buildings, and the second, and more difficult, to endeavour to get rid of the smoke nuisance in buildings that now exist. So far as new building is concerned, over eighty local authorities, including the councils of most of the large cities, have passed resolutions supporting certain proposals for the prevention of new smoke. One of the most important of these is to require the approval of a special authority before new fuel-burning plant is installed in industrial premises. This method, which has found a wide acceptance in the United States, has also during the last seven years been followed in a voluntary way at Birmingham, where, on plans for new buildings being deposited with the surveyor's department for approval, they are passed on to the public health department for "observations," thereby affording an opportunity for discussion and suggestion concerning the suitability of fuel-burning plant from the point of view of smoke prevention.

The larger ogre to be combated, however, is domestic smoke. The ten million chimneys of the homes of England are responsible for about two-thirds of the total nuisance. If clean air is to be enjoyed in the urban parts of this country something must be done about the domestic open fire. The open coal-fire grate is entrenched not only in house architecture but in sentiment, and although gas fires and electric heaters have their place, nothing short of a revolution will dislodge the open fire from the main living-room. Indeed, did not the recent committee of the Royal College of Physicians, in its report on new housing, concede one open fire for each house? From a recent address delivered by a fuel expert to the Women's Advisory Panel of the Domestic Fuels and Appliances Committee, which is advising the Government on fuel economy, we

⁵ *J. Physiol.*, 1941, 99, 467.

⁶ *Arch. Neurol. Psychiat.*, Chicago, 1937, 37, 286.

gather that the solid-fuel industry is concerned in evolving a fire grate which will make unnecessary the sooty flurry that attends the lighting of the fire every morning. A grate is being constructed in which the fire can be so banked up at night that a touch of the bellows will rekindle it within a few moments. Along with this goes another development towards the production of some appliance for burning coal or one of its derivatives smokelessly or almost so. These two inventions when they arrive will make the solid-fuel industry complementary to the gas and electric industries and will do away with the stigma at present attaching to the open coal-fire that it causes atmospheric pollution.

These improvements relate mainly to future building. There remains the problem of getting rid of the smoke from which we at present suffer. This must be gradual, but it need not be slow. One proposal is to establish smokeless zones in the centre and new areas of towns as the first stage of planning for the total abolition of smoke, these areas to be enlarged as fuel appliances for the necessary replacements become available. If this is done, the secretary of the Smoke Abatement Society (surely the Society might change its name to "prevention" or "abolition") thinks it not too sanguine to foretell a smokeless Britain within ten years. One outstanding difficulty may well be railway smoke, on which subject those who live near the main lines of railways could say a great deal. Electrification has gone some way to solve the problem and may go still further, but we cannot see electrification being introduced for a long time to come in the goods traffic marshalling yards of railways, which will remain the final lairs of the twin dragons of smoke and noise.

POISONING FROM HAIR DYE

Since the introduction of coal-tar dyes into the fur industry in 1888 and the subsequent widespread use of one in particular—paraphenylenediamine—as a dye for human hair, there have been many reports of poisoning by this substance. The first toxic effect noted was dermatitis, an epidemic occurring in London in 1922 among women wearing coats with fur collars. During the investigation stimulated by these cases it was found that dermatoses were very frequent among workers in the fur industry, and were due in general to the oxidation dyes and in particular to an intermediate product formed in the course of the oxidation. The dermatoses were in most cases allergic. In a recent investigation of the fur industry in New York¹ these findings have been again confirmed, and patch tests showed in the great majority of cases a hypersensitivity to paraphenylenediamine. The distribution of the rash was variable, beginning generally on the hands, sometimes on the face, arms, trunk, or legs. More serious than the skin-irritant property of paraphenylenediamine, or even than its capacity for producing bronchial asthma—also probably an allergic phenomenon—is its systemic toxic effect, especially on the central nervous system. In acute poisoning the neurological symptoms—dizziness, nystagmus, tinnitus, vertigo, and diplopia—predominate, while in fatal cases acute and subacute necrosis of the liver and severe congestion of the viscera have been found. In one case at least a fatal anaemia has been attributed to the use of a hair dye containing paraphenylenediamine.

Although neurological complications, including papilloedema, retinal haemorrhages, and even optic neuritis, have been described in a number of cases, the actual effects of the poison on the central nervous system have been fully investigated only recently, and the histopathological

changes reveal an interesting link with the earlier post mortem appearances of the liver.² In the case described that of a woman who had used "ursol," a paraphenylenediamine hair dye, for eighteen months, the chief neurological signs were asthenia, drowsiness, muscle tenderness, slightly exaggerated deep reflexes, left ankle clonus, absence of abdominal reflexes and plantar responses. There was also low-grade fever, glossitis, yellow-greyish discoloration of the skin, albuminuria, and severe anaemia. The patient's condition gradually deteriorated, and she died about nine months from the onset of symptoms. At necropsy gross hepatosplenomegaly was observed, and microscopic examination of the liver showed areas of atrophy and local necrosis. In the central nervous system pathological changes in the nerve cells indicated both primary and secondary changes as the result of the paraphenylenediamine poisoning. The most important of these was the deposition of peculiar pigment granules in the nerve cells of the pallidum, the striatum, the hypothalamus, and the dentate nucleus. These were regarded as an "oxidase" reaction due to the direct action of the toxin circulating in the blood stream. Changes considered secondary to the involvement of the liver were deposits of iron pigment, the presence of Alzheimer glia cells, and chromatolysis. As in the case of so many other toxic organic compounds, it appears that the very property which makes paraphenylenediamine industrially effective—that is, its readiness to oxidize into a fixed discoloration—confers upon it its essential toxicity—the capacity for being readily oxidized by the blood and tissues of the living organism.

FAMILIAL MORTALITY AND SCHIZOPHRENIA

Dr. S. Rosenzweig and Mr. D. Bray, of the State Hospital, Worcester, Mass., raise an interesting point in a recently published paper,³ which is mainly statistical. In a comparison of samples of schizophrenics, manic-depressive patients, general paralytics, and normal subjects, families of the first-named showed a higher frequency of instances in which one at least of the siblings died within the subject's lifetime and before he (the subjects were males) reached the age of 19. Anyone familiar with the pitfalls of selection—namely, biased or possibly biased sampling—naturally insists on a critical analysis of the evidence. The authors have taken pains and had the advice of a statistician in the United States Bureau of the Census; we think the conclusion drawn is justified by the evidence. One statistical result probably needs control. The authors find that in the families of the schizophrenics 56% of the deaths occurred before the patient was 6 years old, and so only 44% between the patient's sixth and nineteenth birthdays. This result is used as argument in favour of the death having some aetiological importance as a psychological factor of the psychosis. It is to be noted, however, that the proportion of deaths under the age of 6 (taking the last life table of England and Wales for males) is 39 which would occur under the age of 6 is about 56%. Unless the result for schizophrenics is significantly different from that for the other groups, much stress can be put upon it.

The first Inter-American Congress of Surgery will be held at Santiago, Chile, on November 14 with the cooperation of the surgical societies of Argentina, Brazil, Bolivia, Paraguay, Uruguay, and Chile. The Congress has been organized to commemorate the centenary of the University of Chile.

POST-WAR HEALTH SERVICES

RECENT SPEECHES BY THE MINISTER.

In the first week of this month the Minister of Health, Mr. Ernest Brown, gave public addresses in which he referred to the Government's plans for a comprehensive health service, to the need for further improvement in non-institutional medical facilities, both curative and preventive, and to the relation of the individual doctor to the organization of preventive medicine.

At Oxford on Oct. 1, where he was the guest of the Nuffield Provincial Hospitals Trust, the Minister began with compliments to the energy and enthusiasm with which the Trust pursues its aims, and in particular to the work done during the past year, jointly with his Department, in making surveys of the hospital services throughout the country. Under wise guidance, he said, Oxford had come to be regarded as a laboratory in which all manner of experiments in relation to medical and hospital services were being conducted, or as a power-house providing the motive force for developments elsewhere. Two passages from the Minister's speech are quoted here because they seem to go beyond the matter in which the Oxford audience was primarily concerned.

A Comprehensive Medical Service

"Since we met a year ago developments have occurred in relation to the post-war health services generally which have tended to overshadow the purely hospital aspect of the health problem. It has, of course, been clear to me from an early stage—as I am sure it has been clear to the Trust and to every group of careful observers—that there is room for improvement in the non-institutional as well as in the institutional medical services. Sir William Beveridge's report brought this aspect of affairs before the eyes of many who had not previously been aware of it, and at the same time gave an impetus to our plans for post-war reform. As you know, the Government at once accepted Sir William Beveridge's 'Assumption B'—the provision of a comprehensive health service—and instructed the Secretary of State for Scotland and myself to go in detail into the methods by which their decision might best be implemented. Accordingly we have during the earlier part of this year been engaged in a series of informal and non-committal—but none the less useful—discussions with representatives of the medical profession, the local authorities, and the voluntary hospitals."

"Naturally enough, perhaps, in discussions of this kind, there have been unfruitful as well as fruitful passages. Unfortunate though it may appear, unfounded suspicions about the Government's intentions have given rise to still more unfounded misstatements, which have in turn engendered unnecessary resolutions. Hard words have been said about politicians—not that the politicians will take offence, for they are perfectly accustomed to this method of relieving the feelings. I am confident that this is a passing phase, and that when the Government's proposals are published, and informed criticism and debate become possible for the first time, a calmer atmosphere and wiser counsels will prevail. Criticism of proposals which are not known can scarcely fail to be unfruitful. There is now in preparation a White Paper, which will serve as a basis for public discussion before the next stage of legislation. With the issue of the White Paper debate can usefully begin; until then it is wiser to suspend judgment."

The Promotion of Health

In his inaugural address at Westminster Hospital Medical School on Oct. 4 the Minister took the opportunity to consider some aspects of the future of the national health services. He recalled that the Act which created the Minister of Health twenty-four years ago defined his duties as those of "the promotion of the health of the people." What was this phrase likely to mean in the future, both in general terms and from the point of view of the individual doctor?

Curative Medical Services

The first aspect of the promotion of health, and the one that had bulked largest in history, was that of healing the sick. In this country a vast apparatus of curative services had been built up, originally by private enterprise and voluntary effort, more recently by public action. In the front line was the general practitioner attending and treating his patients either privately or under the National Health Insurance scheme. To support and help him were the consultant and specialist, with all the resources of the voluntary and municipal hospitals, and all the skill of the nursing and other ancillary professions. Scientific advances were constantly being made—we were in the midst of one now with the remarkable developments of chemotherapy. By all the tests that could be applied the results were good—for example, even within the

limits of the present century there had been a fall of 31% in the crude death rate, and in a hundred years it had been halved. But in spite of the quality and range of the curative services we were not making the best possible use of the brains and hands and equipment available. Indeed, how could we have done so?—for hitherto no one had been charged with the specific responsibility of making sure that quantity and distribution of the services were such as to enable every member of the community to enjoy their use whenever required. There were other defects too, giving rise to other queries. If the services were inadequate in quantity, could reorganization effect improvements? Was there room for more co-operation and less competition? All these questions had become more and more insistent of recent years, largely, he suggested, because planning and development of the curative services had lagged behind those of other aspects of the health service. That was why the Government had accepted Assumption B of the Beveridge report and had put its hand to the task of creating a truly comprehensive service. What the exact form of the service would be, and how it would immediately affect the individual doctor or the individual hospital, remained for discussion after the forthcoming White Paper had been issued.

"But from the point of view of long-term development some general implications seem clear—the integration of all hospitals in a common service, the development of fuller consultant and specialist services based on the hospitals, closer team-work between general practitioners, assisted perhaps by the creation of health centres. Changes like these may appear to mean some loss of freedom. I would suggest that the true liberty of the professional man is freedom to exercise his knowledge and his skill according to his conscience and his ability, without fear or favour."

The Preventive Services

The second branch of the promotion of health was one of more modern growth—that of preventive medicine. Historically it first emerged as the prevention of disease by improvement of the human environment. In this sense the nineteenth century was the great era of preventive medicine, for the environment of the huge new urban population created then new problems of disease on a much vaster scale, and necessitated the organization of prevention as a more effective alternative to cure—the building of the sewer instead of the pest-house. Removal of nuisances, drainage, water-supply, housing, town-planning—that was roughly the order in which preventive medicine tackled the problems. The results were almost staggering; they surpassed even the triumphs of curative medicine. Cholera had long been unknown; there had been no deaths from typhus for twenty years; the death rate per million from enteric fever had fallen from 370 to 2 in the last seventy years. More recently preventive medicine had branched out in a new direction. After the Boer War the school medical service was founded to watch over the health of school children. Later the maternity and child welfare service was put on a more regular footing to perform the same function in relation to pregnant women and young children. Thirty years ago the tuberculosis service began to get under way, one of its objects being to trace contacts, to stop the spread of the disease, or to check it at the earliest stage. None of these types of activity, any more than vaccination against smallpox or immunization against diphtheria, was primarily curative; nor were they environmental, though they all embodied the preventive principle. The essence of each was that it represented the application of preventive medicine personally to individuals. A third aspect of preventive medicine had given rise to the phrase "positive health." The questions asked in relation to disease: "What is the cause of this condition? and what is the treatment for it?" led on naturally to a third question: "How can the recurrence of this condition be prevented?" The developments of preventive medicine had reworded the last question in a new form: "How can individual health be promoted by positive action so that this condition will not occur at all?" This was a field which in many ways we were only beginning to explore, though we knew some of the answers to a few of the ramifications of the question.

The Family Doctor and Preventive Medicine

Some of the problems involved, Mr. Ernest Brown said, raise broad questions of social policy—housing, agriculture, foreign trade, taxation. On these the individual doctor as citizen had his part to play, a part which could not fail to be important owing to the professional weight attaching to his views. But as a doctor even more than as a citizen he must be closely concerned with the promotion of health.

"Some of the profession will, of course, be in contact as experts with environmental problems—the medical officer of health, the bacteriologist. What I have in mind, however, is rather the general practitioner, the family doctor, and his relationship to prevention. Here there is one reform we must work for, and that is to bring together again the family doctor and those personal preventive services like child welfare and the care of pregnancy, which have tended to develop along increasingly divergent courses. That is one reason why it is so essential to plan for a comprehensive

service which provides a family doctor for those many families that have hitherto been without one. Another reason is that the general practitioner can and will have a most important role in putting across to the individual citizen the principles of positive health. We are gradually realizing the importance of health education, and we are gradually learning more effective ways of catching the ear and the eye of the public at large. But in bringing home to the parent or adolescent or child the principles of healthy living there is no method so effective as that of personal contact and individual advice, and no adviser so effective as the family doctor. My hope is therefore that, on the firm foundation of comprehensive curative medical facilities available to every citizen, we shall be able to build a health service with the positive promotion of health as its foremost object."

Nova et Vetera

COS AND HIPPOCRATES A HISTORICAL REVISION

The events of the war have brought Cos into the news. Inevitably there comes to memory the name of its great medical son. Hippocrates of Cos has always been revered as the father of medicine. The extensive, interesting, and beautiful literature in his name has attracted scholars in every generation. From these great books, from ancient traditions, from contemporary and later references, from various material remains, from the results of excavations, from ancient but relatively late and unauthentic "lives," and perhaps not least from their inner consciousness, medical writers have evolved the character of the ancient Greek physicians as exemplified by their great progenitor. Unquestionably this picture, which has existed for at least 2,000 years, is a very moving one. It has proved to be of highest ethical value to practitioners through the ages.

Can we still treat this picture as accurate in the photographic sense? Was there really a physician of Cos, Hippocrates, who lived from about 460 to about 360 B.C.? Did he learn his art on his native island, where it was taught him in the purest form by priests in a temple of Aesculapius? Did he practise over many parts of the Greek world with the greatest success, gaining the respect of all men for his character and attainments? Did he write many of the works in the great "Hippocratic Collection"? Has his likeness after the flesh really come down to us in the well-known bust, the features and expression of which seem to suggest a wise and thoughtful man pondering human ills?
